Acute severe asthma

David V Tuxen and Matthew T Naughton

Acute severe asthma is a medical emergency associated with a significant morbidity and mortality. Many of the adverse outcomes are attributed to underestimation of severity with delayed and/or inadequate treatment[1–3] and are potentially preventable.

The worldwide prevalence of asthma varies widely (2–37 % in children),[4] but is increasing worldwide[5–7] with life-threatening episodes affecting an estimated 0.5% of asthmatics per year.[8] Australia, New Zealand and UK have amongst the highest incidences.[6,7] In Australia, 9% have asthma as a long-term condition[9] and up to 40% of children have asthma symptoms at some time.[5] Although the prevalence of asthma is increasing, many countries have achieved reductions hospital presentations and admissions,[10,11] reduced intensive care admissions and reduced overall asthma mortality.[10,11] Improved community management of asthma,[1,2] more widespread use of inhaled corticosteroids[3] and other preventative measures such as action plans have been given the credit for these improvements. Improved intensive care asthma management has resulted in less requirement for mechanical ventilation and decreasing mechanical ventilation mortality (**Fig. 35.1**).[10,11] These changes have resulted in the group of asthma patients who require mechanical ventilation having more severe asthma, that is more refractory to treatment and more difficult to manage.[12,13] Despite reducing admissions, significant and potentially preventable mortality continues to occur in those patients who do require intensive care or mechanical ventilation[12,14,15]

CLINICAL DEFINITION

Asthma has been defined as a lung disease with the following characteristics[16]: (i) airway obstruction that is reversible (completely or partially) either spontaneously or with treatment, (ii) airway inflammation, and (iii) increased airway responsiveness to a variety of stimuli. Exacerbations of asthma are characterised by increasing dyspnoea, cough, wheeze, chest tightness and decreased expiratory air flow. Status asthmaticus has had varying definitions. However, for practical purposes, any patient not responding to initial doses of nebulised bronchodilators should be considered to have status asthmaticus.[17]

'Difficult' (as opposed to 'severe') asthma is another term in which patients can present with mild, moderate or severe asthmatic symptoms. Characterisations can include: (a) discordance between symptoms and objective markers of asthma such as lung function or arterial blood gases, (b) severe asthma despite treatment that should be effective, (c) a disconnection between patient expectations and effective outcomes.[18] Commonly, there is poor compliance, psychosocial adversity and secondary gain with continued symptoms. Significant anxiety, social and adverse family circumstances frequently coexist. Differential diagnoses include hyperventilation syndromes, vocal cord dysfunction, COPD or lack of adherence to treatments (estimated to occur in two-thirds of patients presenting). An alternative description includes poor perceivers or over-reactors. These patients are difficult because sometimes they present with severe life-threatening asthma, yet experience would suggest this to be preventable if the usual medication were taken.

AETIOLOGY

The pathogenesis of asthma is complex with both genetic and environmental influences. The increase in asthma prevalence has been attributed to the 'hygiene hypothesis',[19] which suggests that reduced exposure to childhood infections as a result of antibiotics and hygienic lifestyle promotes an imbalance in T-cell phenotype leading to inflammatory cytokine overproduction. IgE-dependent mechanisms appear to be particularly important in generating the characteristic state of airway inflammation and bronchial hyperreactivity with the allergens in the local environment dictating the specificity of the antibody response.[20] Triggers of acute asthma can be non-specific (cold air, exercise, atmospheric pollutants), specific allergens (housemite, pollen, animal danders), modifiers of airway control (aspirin, beta blockers), or stress or emotion. No precipitant can be identified in over 30% of patients.

A wide range of risk factors for life-threatening asthmatic episodes and/or the need for mechanical ventilation are now recognised. First is *underestimation of severity*, with delayed and/or inadequate treatment by managing doctors and/or the patient.[1–3] Secondly, *patient behaviour factors* that are associated with the

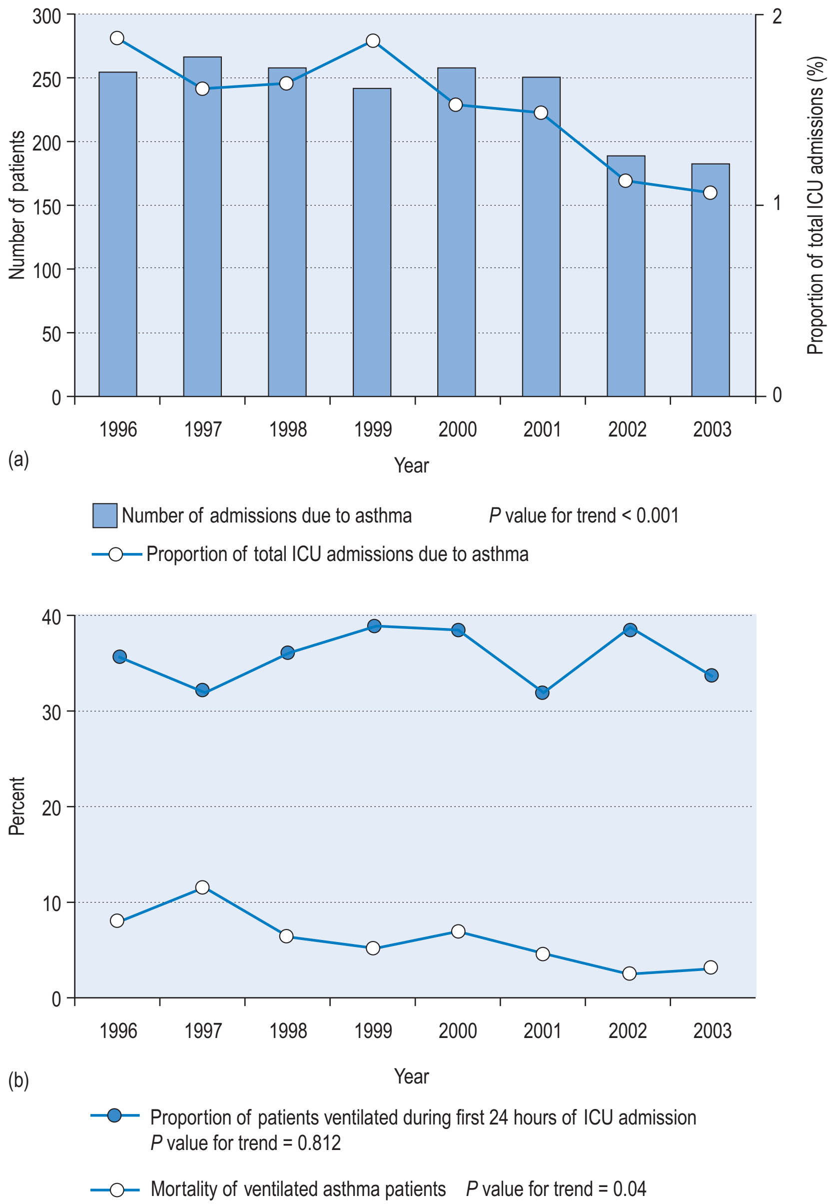

Figure 35.1 ICU admissions, mechanical ventilation and mortality due to asthma in Australia from 1996 to 2003. *(Modified from Stow P, Pilcher D, Wilson J, et al.*[10]*)*

requirement for mechanical ventilation are smoking (and illicit drugs), poor treatment compliance, prior treatment with beta agonists without inhaled steroids.[12,21] Low socioeconomic status has also been recognised as a risk factor. Thirdly, *genetic polymorphism* (the IL4RA*576R allele) is now recognised as a significant factor related to fatal or near-fatal asthma attacks.[13,22] Other functional factors linked to severe asthma attacks include airway remodelling, down-regulation of β-receptors, and lack of steroid responsiveness.[13] Diminished perception of dyspnoea in some patients with acute severe asthma leads to delayed interventions.[13,23]

PATHOPHYSIOLOGY

The post-mortem airway pathology of patients who die from acute asthma includes bronchial wall thickening from oedema and inflammatory cell infiltrate, hypertrophy and hyperplasia of bronchial smooth muscle and submucosal glands, deposition of collagen beneath the epithelial basement membrane and prominent intraluminal secretions. These secretions may narrow or occlude the small airways, and post-mortem studies frequently report extensive plugging and atelectasis.[24,25] When interpreting the latter findings it is important to remember that during life in very severe asthma the

lungs are hyperinflated to close to total lung capacity (TLC) by maximal inspiratory effort and to beyond TLC during mechanical ventilation. At this time radiological atelectasis is rare, suggesting that most airways are communicating at these high lung volumes, even if airways are very narrowed. Only at death does the prolonged apnoea allow lung deflation, widespread airway closure and alveolar gas absorption to give the post-mortem appearance of extensive complete occlusion that was not present to the same degree during life.

In some deaths bronchial mucus is absent; in these cases airway obstruction may be mainly due to intense smooth bronchoconstriction. This observation may account for two patterns of progression of asthma:

1. Acute severe asthma is the more common group (80–90%), with progression of symptoms over many hours or days, often with a background of poor control and recurrent presentations. Most patients in this group are female, with upper respiratory infections are frequent triggers; it responds more slowly to treatment, which may reflect greater contribution from mucous inspissation and chronic bronchial wall inflammation with eosinophilia.[23,26]
2. 'Hyperacute', 'fulminating', 'asphyxic' or 'sudden onset' severe asthma is where the interval between onset of symptoms and intubation is less than 3 hours.[23,26–28] This presentation is less common (approximately 10–20% of life threatening presentations), tends to occur in younger patients with relatively normal lung function but high bronchial reactivity, and the majority of patients are male. Massive respiratory allergen exposure, cold air or exercise and psychosocial stress are the most frequent triggers.[23] This group characteristically has neutrophilic inflammation, typically responds quickly to bronchodilators and is thought to be mainly due to bronchial smooth muscle contraction.

The characteristic pathology of asthma leads to increased airway resistance and dynamic pulmonary hyperinflation. This has a number of consequences:

- *Increased work of breathing* results from increased airway resistance and reduced pulmonary compliance as a result of high lung volumes. When asthma is severe, dynamic hyperinflation may bring the lung volume close to total lung capacity.[29] This causes a severe mechanical disadvantage of inspiratory muscles with diaphragm flattening and results in a large inspiratory muscle effort affecting a small change in inspiratory pressure. The final outcome can be respiratory muscle failure with insufficient alveolar ventilation and consequent hypercapnia.[30]
- *Ventilation–perfusion mismatch* is the result of airway narrowing and closure. This leads to impaired gas exchange and increases the minute ventilation requirement, further adding to the work of breathing.[30]
- *Adverse cardiopulmonary interactions* are seen when the marked changes in lung volume and pleural pressure impact on the function of both left and right ventricles.[31,32] Spontaneous breathing during acute asthma can generate inspiratory pressures as low as –35 cmH_2O.[31,32] This increases venous return to the right ventricle (RV) and increases RV volume during inspiration. However, increased RV afterload as a result of hypoxic pulmonary vasoconstriction, acidosis and increased lung volume[31,32] and increased pulmonary capacitance decrease return to the left ventricle (LV). These negative intrapleural pressures also cause increased LV afterload[31,32] and increased RV afterload with septal shift reduces LV volume[31,32] further reducing LV output during inspiration. Pulsus paradoxus is the most direct result of these cardiopulmonary interactions in severe asthma. This is a decrease in systolic blood pressure during inspiration of >10 mmHg (1.33 kPa), typically 15–25 mmHg (2–3.33kPa), normal ≤5 mmHg (0.66kPa). The degree of pulsus paradoxus may not correlate with the severity of asthma as it may be reduced by inspiratory muscle weakness or fatigue.

CLINICAL FEATURES AND ASSESSMENT OF SEVERITY

The symptoms of asthma are well known and include wheeze, cough, dyspnoea, and chest discomfort or tightness. Triage and assessment of severity of the acute asthma attack are crucial. Underestimation or non-measurement of asthma severity is associated with increased mortality.[33,34] Assessment has two key features: assessment of initial severity and ongoing assessment of response to treatment:

History Any history of prior intubation and mechanical ventilation for asthma is a predictor for life-threatening asthma.[33,34] A history of poor asthma control, multiple recent medical presentations for asthma and poor response to prior treatments are recognised risk factors. Other risk factors are listed above (see Aetiology).

Physical examination The general appearance and level of distress can be an important indicator of severity (**Table 35.1**). Use of accessory muscles, suprasternal retraction, markedly diminished breath sounds or a silent chest, central cyanosis, inability to speak, a disturbance in the level of consciousness, upright posture and diaphoresis all suggest a severe attack.[35] A respiratory rate >30/min, pulse rate >120/min and pulsus paradoxus of >15 mmHg (2 kPa) are associated with severe asthma though their absence does not preclude life-threatening asthma. Patients with diminished perception of dyspnoea may mask severe asthma and lead to underestimation of severity.[13,23]

Ventilatory function tests The patient may not be able to perform these due to breathlessness. However, FEV_1 and peak expiratory flow rate (PEFR) are useful

Table 35.1 Assessment of asthma severity

	MILD	MODERATE	SEVERE
Conscious state	Alert, relaxed	Anxious, difficulty sleeping	Agitated, delirious
Speech	Sentences	Phrases	Words
Accessory muscles	Nil	Mild	Significant sitting upright
Wheeze	Moderate	Loud	Loud or silent
Pulse rate (BPM)	<100	100–120	>120
Peak expiratory flow (% predicted)	>80%	60–80%	<60%
Pa_{CO_2} (mmHg) (kPa)	<45 (5.98)	<45 (5.98)	>45 (5.98)

Pulsus paradoxus when present indicates severe asthma; however, it is an unreliable test.

indicators of severity and response to treatment when done serially. An FEV_1<1.0 litre or PEFR<100 L/min indicates very severe asthma at significant risk of requiring mechanical ventilation. In some patients forced expiration may worsen symptoms; these measurements should cease if this occurs.[36]

Pulse oximetry Pulse oximetry is usually readily available and provides a rapid assessment of oxygenation. It is also very valuable in regulation oxygen therapy, both for avoiding hypoxia (Sp_{O_2}>90%)[37] and for avoiding potential side-effects of hyperoxia (Sp_{O_2}<95%).[38] Of course, pulse oximetry cannot assess arterial P_{CO_2} or acid–base state and so does not replace the need for blood gases.

Arterial blood gases Arterial hypoxaemia is almost invariably present in a patient with severe asthma breathing room air though it usually responds well to low-level oxygen supplementation (28–35%).[37] Blood gases should not delay initiation of treatment, and are not required in mild asthma or moderate asthma that is responding well to treatment. They are very important in severe asthma, or moderate asthma with inadequate treatment response. The Pa_{CO_2} is an important measure of severity and, if hypercapnia is present, an important guide to treatment response.

Ventilation is initially increased in an acute attack leading to hypocapnia and a respiratory alkalosis.[37] As the asthmatic attack worsens, the work of breathing, V/Q mismatch and adverse cardiopulmonary interactions all increase, and the minute ventilation required to maintain the same alveolar ventilation and Pa_{CO_2} increases. Eventually the patient is incapable of meeting this demand and the Pa_{CO_2} rises. The presence of hypercarbic acidosis is associated with a FEV_1 of <20% predicted and reliably indicates that asthma is severe. A metabolic acidosis may also be present, and this is most commonly due to lactic acidosis[39] associated with intravenous or continuous nebulised beta agonists.[40,41]

Chest X-ray Although not generally helpful in assessing severity,[42] a chest X-ray should be performed when asthma is severe or refractory to treatment, when barotrauma or lower respiratory tract infection is suspected or when the diagnosis is in doubt. It is not required in milder attacks that respond well to treatment.

Assessment of treatment response Repeated evaluation of the patient's response to treatment is a valuable tool in assessing severity of acute asthma. The response to the first 2 hours of treatment is an important predictor of outcome.[43] Adverse events are associated with underestimation of severity, inadequate observation after initial assessment and under treatment. Ongoing evaluation of response to therapy is critical. This evaluation should include repeated assessments of: (i) appearance and physical indicators of severity (see Table 35.1); (ii) objective measurements – FEV1 or PEFR, heart rate, respiratory rate, pulsus paradoxus; (iii) Sp_{O_2} and oxygen requirements; (iv) progress of Pa_{CO_2} or metabolic acidosis if present on blood gases.

Admission to intensive care is preferred if the above criteria suggest severe asthma. Indications for immediate admission to intensive care include respiratory arrest, altered mental status, dysrhythmias or associated myocardial ischaemia.

DIFFERENTIAL DIAGNOSIS

The diagnosis of asthma is usually obvious. However, wheeze and dyspnoea may be caused by other illnesses including left ventricular failure, aspiration, upper airway obstruction, inhaled foreign body, pulmonary embolism or hyperventilation syndromes. Wheeze and dyspnoea arising in hospitalised patients who were not admitted with asthma are less likely to be due to asthma. Clues to another or additional diagnosis include: (i) no past history of asthma; (ii) sudden onset following vomiting or food intake; (iii) focal or asymmetrical chest auscultation findings; (iv) risk factors for thromboembolism; (v) onset during hospitalisation when admitted with another condition.

MANAGEMENT

ESTABLISHED TREATMENTS

Initial therapy of acute severe asthma should include the following.

OXYGEN

Hypoxaemia contributes to life-threatening events that complicate acute severe asthma.[44] Humidified supplemental oxygen should be titrated to achieve a Sp_{O_2}>90%. The risk of oxygen-induced increasing hypercapnia with coexisting chronic air-flow limitation

or pre-existing chronic hypercapnia is a well-known reason to maintain a lower Sp_{O_2} (eg. 90–92%). This phenomenon was not believed to be relevant to the majority of patients with acute asthma; however, there is now emerging evidence that hyperoxia may be harmful to a more widespread group[45] by releasing pulmonary hypoxic vasoconstriction, worsening V/Q matching and increasing hypercapnia. A recent randomised controlled trial[38] showed a decrease in Pa_{CO_2} in a group receiving 28% O_2 and an increase in Pa_{CO_2} in a group receiving 100% Fi_{O_2}.

BETA AGONISTS

Short-acting beta agonists remain the first-line bronchodilator therapy of choice.[4,46–48] Agents include salbutamol (albuterol), terbutaline, isoproterenol (isoprenaline) and epinephrine (adrenaline). Salbutamol is generally the agent of first choice as it has relative β_2-selectivity, with decreased β_1-mediated cardiac toxicity. Long-acting beta agonists such as salmeterol have no role in status asthmaticus owing to slow onset of action and association with fatalities in this setting.[17] Beta agonists cause bronchodilatation by stimulation of β_2-receptors on airway smooth muscle and may reduce bronchial mucosal oedema.[49]

The standard approach is to start with nebulised salbutamol in high and repeated doses.[50] The typical adult dose is 5–10 mg (in 2.5 to 5.0 mL diluent volume) every 2–4 hours, but more frequent doses with a higher total dose are often required in severe asthma. It should be noted that less than 10% of the nebulised drug reaches the lung even under ideal conditions.[51] Continuous nebulisation appears to be superior to intermittent doses and is commonly used at the beginning of treatment in severe asthma.[17,52] The nebuliser should be driven by oxygen with the flow at 10–12 L/min and a reservoir volume of 2–4 mL so as to produce particles in the desired 1–3 μm range.[53] The total dose should be modulated by response to treatment and the level of toxic side-effects.

Beta agonists can also be delivered by metered dose inhaler (MDI). There are data to suggest that, in non-intubated patients, MDIs combined with a spacing device are as effective as or more effective than nebulisers and are cheaper to use.[54,55] In intubated patients both nebulisers and MDIs have been used effectively.[56] Two-thirds of acutely presenting patients will respond well to inhaled beta agonists[57] irrespective of the method of administration. The remaining one-third are refractory even to high doses and usually require longer periods of intense treatment including multiple other agents.

Intravenous beta agonists remain controversial. There is no clear evidence of benefit[58] and significant side-effects. Despite this, intravenous beta agonists have a theoretical benefit of additional access to lung units with severe air-flow obstruction and poor nebulised drug delivery and some studies have demonstrated improved response when intravenous beta agonist is used.[59] Intravenous beta agonists continue to be considered if the patient is not responding to continuous nebulisation.[60] The typical dose is 5–20 μg/min, but doses >10 μg/min should be used with caution because of side-effects, which should be monitored closely. Salbutamol 100–300 μg may also be given intravenously to non-intubated patients in extremis or delivered down an endotracheal tube should there be no time to gain i.v. access.

Side-effects of beta agonists include tachycardia, dysrhythmias, hypertension, hypotension, tremor, hypokalaemia, worsening of ventilation–perfusion mismatch and hyperglycaemia,[61] but the most common side-effect of parenteral beta agonists occasionally seen with continuous nebulised beta agonists is lactic acidosis. This occurs in over 70% of patients, has an onset within 2–4 hours of commencing an infusion or following a intravenous statim doses, levels may reach 4–12 mmol/L and may significantly add to a respiratory acidosis and respiratory distress.[41,62,63] Parenteral infusions should be initially limited to 10 μg/min and statim doses should not exceed 250 μg. Serum bicarbonate and lactate should be regularly monitored. If lactic acidosis becomes significant, the salbutamol infusion should be reduced or ceased. Lactic acidosis will generally resolve within 4–6 hours of infusion cessation and is seldom a problem with infusions in place for more than 24 hours.

Long-term high-dose beta-agonist use has been associated with increased mortality,[64] but whether high-dose beta agonists are a marker of disease severity, an indicator of suboptimal inhaled steroids or a direct cause of death is unclear. These concerns do not apply in the treatment of the acute asthma attack.

ANTICHOLINERGICS

Anticholinergics cause bronchodilatation by decreasing parasympathetic-mediated cholinergic bronchomotor tone.[65] Ipratropium bromide is the most commonly used anticholinergic for asthma and is a quaternary derivative of atropine. Although some conclude there is insufficient evidence,[66] a number of studies and meta-analyses suggest clear additional benefit and few side-effects when ipratropium bromide is added to the beta-agonist regimen.[67,68] Ipratropium is now widely used as first-line therapy for acute severe asthma in conjunction with beta-agonist therapy. Preservative-induced bronchoconstriction has been reported in a few patients and can be prevented by using preservative-free solutions.[69] The bronchodilatation effect of ipratropium bromide appeared to be maximal with a dose of 250 μg when studied in children between 9 and 17 years of age. The optimal dose is not known in adults; a reasonable regimen would be to add 500 μg of ipratropium bromide to the salbutamol nebuliser every 2– 6 hours; however, initial dose intervals as low as 10–20 minutes have been recommended.[70]

CORTICOSTEROIDS

The role of corticosteroids in the acute asthma attack has been well established. Systemic steroids should be considered in all but mild exacerbations of asthma.[48] Their benefits include increased β-responsiveness of airway smooth muscle, decreased inflammatory cell response and decreased mucus secretion. Early treatment with corticosteroids has been shown to decrease the likelihood of hospitalisation and decrease the mortality rate from acute asthma. Systematic reviews[48,71] suggest that effects commence within 6–12 hours, that oral is as effective as intravenous, and that there is little evidence of benefit for initial daily doses exceeding 800 mg/day of hydrocortisone (160 mg/day methylprednisolone) given in four divided doses.

Inhaled steroids have established long-term benefit and are believed to be a major factor in asthma mortality reduction.[1–3] Although some believe there is insufficient evidence,[66] there are data that inhaled steroids may also have a role during an acute attack[72,73] and it appears reasonable to use them routinely from day one as they may also enable more rapid dose reduction of parenteral steroids, potentially reducing side-effects.

Parenteral corticosteroid dose reductions should commence after 1–3 days according to the severity of the attack, the degree of chronic inflammation and the response to treatment and should be converted to a reducing dose of oral steroids within 4–7 days (e.g. oral prednisolone starting at 40–60 mg per day).

Side-effects of corticosteroids include hyperglycaemia, hypokalaemia, hypertension, acute psychosis and myopathy,[74,75] though they are usually well tolerated acutely. The immunosuppressive effects can increase the risk of infections including *Legionella*, *Pneumocystis carinii* and varicella[76,77] especially when the patient is on long-term corticosteroids. Allergic reactions including anaphylaxis have been reported with the use of most corticosteroid preparations.[78]

AMINOPHYLLINE

There have been conflicting reports regarding the efficacy of aminophylline in acute asthma ranging from no benefit[78] to improved lung function and improved outcome.[79] However, it is accepted that aminophylline is an inferior bronchodilator, with a narrow therapeutic range and frequent side-effects[80] including headache, nausea, vomiting and restlessness, with cardiac arrhythmias and convulsions that can occur at serum levels above 200 μmol/L (40 mg/L).

As a result, aminophylline is not a first-line treatment.[47,48,60,66] Aminophylline may be given to patients with acute asthma who are not showing a favourable response to full treatment with first-line agents. Careful administration and monitoring are required with an initial loading dose of 3 mg/kg (maximum 6 mg/kg, omitted if the patient is already taking oral theophylline) and an infusion of 0.5 mg/kg/h. This should be reduced in patients with cirrhosis, cardiac failure or chronic obstructive airways disease and in patients taking cimetidine, erythromycin or antiviral vaccines. Drug levels should be taken after a loading dose (if given), and then 24 hours later aiming for a level of 30–80 μmol/L (5–12 mg/L). Levels should be repeated daily thereafter until stability has been achieved. The duration should be based on the response to treatment.

NON-ESTABLISHED TREATMENTS

A number of other therapies have reported benefit in acute severe asthma, but their role in addition to full standard therapy has not been clearly established and they are not advocated for routine use. However, these modes of therapy can be considered in the patient who is in extremis or remaining severe despite conventional treatment.

EPINEPHRINE

Epinephrine has some theoretical advantages over pure β_2-agonists in that its additional α-agonist actions of vasoconstriction and mucosal shrinkage may improve airway calibre. However, in practice, nebulised or subcutaneous epinephrine has not been shown to confer any advantage over nebulised β_2-agonists and is not recommended because of its cardiac side-effects.[70] It may be tried in the patient who is failing to respond to conventional treatment. The nebulised dose is 2–4 mg in 2–4 mL (1% solution, 0.05 mL/kg) 1–4-hourly. The subcutaneous dose is 0.2–0.5 mg (0.2–0.5 mL of 1:1000 epinephrine) repeated if necessary 2–3 times at 30-minute intervals. Epinephrine by infusion may avert mechanical ventilation in very severe cases, but should be used with caution with ECG monitoring and preferably with central venous access. An initial i.v. dose of 0.2–1.0 mg (2–10 mL of 1:10000 epinephrine) is given slowly over 3–5 minutes. This may be followed by a continuous infusion of 1–20 μg/min, which is weaned when the acute attack subsides.[81]

MAGNESIUM SULPHATE

Magnesium sulphate is postulated to block calcium channels, and possibly acetylcholine release at the neuromuscular junction, leading to smooth muscle relaxation and bronchodilatation. It appeared to be well tolerated in early studies, and a number of some prospective randomised, double-blind, prospective trials of adding intravenous or nebulised magnesium sulphate to conventional therapy in adults with acute asthma were performed. Some showed benefit whereas others showed no benefit.

Three meta-analyses[82–84] did not support routine use of magnesium and it is not recommended for acute asthma. If given, recommended doses are 5–10 mmol (1.25–2.5 g, 2.5–5.0 mL of 50% solution) given slowly over 20 minutes, but doses up to 40–80 mmol (10–20 g) have been given.[85] Side-effects include hypotension,

flushing, sedation, weakness, areflexia, respiratory depression and cardiac arrhythmias seen at higher serum levels (>5 mmol/dL or 12 mg/dL). Serum concentrations should be measured if repeated or high doses are used.

HELIOX

Inhalation of a helium : oxygen mixture reduces gas density and turbulence with reduced air-flow resistance. The most effective gas mixture is 70% helium (30% oxygen) and the minimum concentration likely to provide benefit is 60% helium. Work of breathing is decreased and pulmonary access of inhaled bronchodilators may be improved.[86,87] Small case-series and reports have suggested benefit from heliox, randomised prospective trials have both positive and negative results.[88,89] Meta-analyses[90,91] have shown trends towards improved aspects of lung function but insufficient evidence to recommend use of heliox in severe asthma. However, it otherwise appears safe and may be tried in critical asthma to avert intubation or during difficult mechanical ventilation provided the patient can tolerate 30–40% O_2.

ANAESTHETIC AGENTS

Ketamine, a dissociative anaesthetic agent, has been used in severe asthma.[92] It may cause bronchodilatation by both sympathomimetic potentiation and a direct effect on airway smooth muscle.[93] Small case-series have suggested some benefit, although a small randomised controlled trial found no benefit with ketamine in the treatment of acute severe asthma[94] – ketamine may be a useful induction agent for endotracheal intubation (dose 1–2 mg/kg) as it may ameliorate the bronchoconstrictor response to intubation. It has been used as a continuous infusion in the dose range of 0.5–2 mg/kg/h[94,95] to treat refractory asthma. Side-effects include increased bronchial secretions, a hyperdynamic cardiovascular response and hallucinations; the hallucinations can be reduced with concomitant benzodiazepines.

The volatile inhalational agents including halothane, isoflurane and enflurane have been used in mechanically ventilated patients with severe asthma.[96] Clinical data are limited to small case-series, and side-effects include direct myocardial depression, arrhythmias and hypotension.[97] The volatile anaesthetic agents should be used with great care and usually only as a prelude to or during invasive ventilation. An anaesthetic machine or custom-fitted ventilator is required for safe administration.

LEUKOTRIENE ANTAGONISTS

Leukotriene antagonists have shown benefit in chronic asthma[98] and there is some evidence of benefit in acute asthma.[99,100] There is insufficient evidence and the benefits were of insufficient magnitude to recommend these agents for acute severe asthma.[66] However, some authors do not exclude them from use in patients refractory to all standard treatments.[101]

BRONCHOALVEOLAR LAVAGE

Bronchoalveolar lavage has been used in severe refractory asthma to clear mucous plugging during mechanical ventilation.[102] It can transiently worsen bronchospasm and hypoxaemia and should be used when air-flow obstruction has stabilised. It may have a role in ventilated patients with resistant mucus impaction, but it is rarely used.

THERAPIES NOT RECOMMENDED

Antibiotics are not routinely indicated[103] unless there is clear evidence of infection. Antihistamines are not effective. Inhaled mucolytics have been shown to have no benefit and may worsen air-flow obstruction. Sedation is unsafe in acute asthma. There is a clear association between their use and avoidable deaths.[104] Patients with severe asthma should not be sedated unless being intubated and ventilated, or in carefully monitored circumstances.

VENTILATION IN ASTHMA

DYNAMIC HYPERINFLATION

In all degrees of air-flow obstruction, slow expiratory air flow results in incomplete exhalation of gas during normal expiratory times. Gas is trapped in the lungs by the arrival of the next breath and the lungs are unable to return their normal passive relaxation volume (functional residual capacity, FRC). Incomplete exhalation of each successive breath causes progressive accumulation of trapped gas called dynamic hyperinflation (DHI, **Fig. 35.2**),[105] which continues until an equilibrium point is reached where the exhaled volume increases to match the inspired volume.[105] This equilibrium occurs because increasing lung volume increases small airway calibre and lung elastic recoil pressure, both of which improve expiratory air flow and allow the inspired tidal volume to be exhaled in the expiratory time available. There are three primary determinants of this equilibrium point: the volume inspired (V_t), the time for expiration (t_e which depends on both the ventilator rate or cycle time and the inspiratory flow or inspiratory time, t_i) and, of course, the severity of air-flow obstruction (the time constant of the lung). The first two determinants are controlled by the ventilator settings and compound to the minute ventilation (V_e) making this the most important determinant of DHI.

Gas trapped at the end of expiration exerts a positive pressure on the alveoli; this pressure is intrinsic positive end-expiratory pressure ($PEEP_i$) or auto-PEEP.[105,106] During expiration, sequential closure of the most severely obstructed airways occurs with only the less obstructed airways remaining in communication with

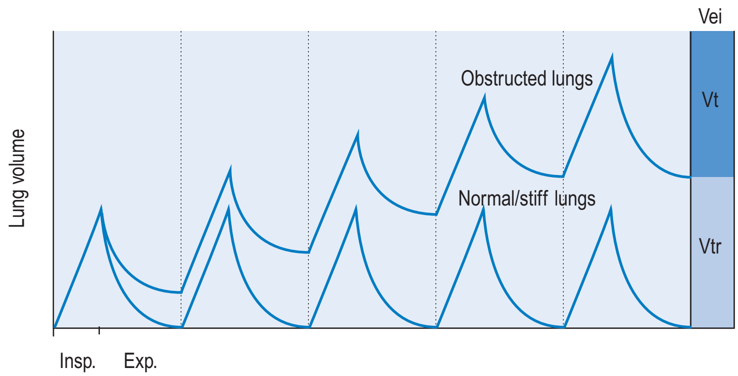

Figure 35.2 Dynamic hyperinflation. The volume history of normal or acutely injured lungs compared with that of obstructed lungs when commenced on controlled mechanical ventilation. This shows initial lung volume to be at the passive relaxation volume of the respiratory system or functional residual capacity (FRC).

the central airway at the end of tidal expiration.[107] As a consequence, measured $PEEP_i$ underestimates the true magnitude of $PEEP_i$ and is recognised as being insensitive to changes in severity.[107]

In mild air-flow obstruction, this process is adaptive as it allows the desired minute ventilation, which could not be achieved at FRC, to be achieved at a higher lung volume (**Fig. 35.3**, mild AO'). As asthma becomes more severe (Fig. 35.3, 'mod AO') the static FRC that would be reached with a long expiratory time is elevated above the normal FRC by airway closure (static hyperinflation) and DHI further increases lung volume to a level where work of breathing is increased by lower lung compliance and respiratory muscles become less efficient from shortening and mechanical disadvantage. At this level some degree of dyspnoea is expected. When asthma is severe enough to risk requiring mechanical ventilation, static hyperinflation may increase FRC by 50%[108] and very little DHI is required to reach total lung capacity (Fig. 35.3, 'severe AO'). In this circumstance, the minute ventilation required to maintain normocapnia would cause hyperinflation beyond normal total lung capacity. During spontaneous ventilation, the patient with severe asthma is unable to exceed total lung capacity (Fig. 35.3), has a much lower maximum minute ventilation capacity and as a result must become hypercapnic even at maximum respiratory effort with no fatigue.[17] When mechanical ventilation is commenced, increased tidal volume and rate delivery is easily able to increase minute ventilation and DHI well beyond normal total lung capacity (Fig. 35.3).[105] The consequences of this are commonly hypotension (due to increased intrathoracic pressure and decreased venous return) and barotrauma.[29,105,108,109]

NON-INVASIVE VENTILATION (NIV)

Non-invasive ventilation (NIV) has been widely used for a variety of respiratory problems.[110] In severe asthma there are a number of potential benefits. Externally applied PEEP may help overcome $PEEP_i$ due to gas trapping and thus reduce the inspiratory threshold work of breathing. Augmentation of inspiration with NIV may further decrease the work of inspiration and increase tidal volume and minute ventilation. If tidal volume is increased with a shorter inspiratory time, then increased minute ventilation can occur without a proportional increase in dynamic hyperinflation. Both inspiratory augmentation and PEEP may facilitate airspace opening, thus reducing V/Q mismatch.[111,112]

The role of NIV is well established in chronic obstructive pulmonary disease where a number of randomised trials have shown benefit.[113,114] Although there have been no large randomised trials in acute asthma, there is increasing evidence of benefit from NIV for this indication with all studies reporting positive outcome.[115,116] Non-randomised studies have reported improvements in respiratory acidosis and respiratory rate following the introduction of NIV, and low requirements for invasive ventilation. In small prospectively randomised studies of acute asthma, Sokorovski et al[116] showed better lung function and decreased hospitalisation rate and Gupta et al[117] found accelerated the improvement in lung function, decreased inhaled bronchodilator requirement, and shortened ICU and hospital stay. In a retrospective cohort study, Murase et al[118] found that NIV reduced the rate of endotracheal intubation from 18% (9/50) to 3.5% (2/57, p=0.01).

There have been multiple reviews of NIV for acute severe asthma.[119–122] All concluded there is limited evidence for some benefits, insufficient data to be conclusive and that larger trials are needed. Where opinions were given, all recommended use if NIV in selected patients with asthma.[120–122] A trial of NIV in patients with acute severe asthma and risk of respiratory decompensation is now warranted in patients who are cooperative and can tolerate the facemask. Indications for use are: (i) moderate to severe dyspnoea or respiratory distress, (ii) hypercapnic acidosis, and (iii) respiratory rate >25, accessory muscle use or paradoxical breathing.[112] Contraindications to NIV include cardiac or respiratory arrest, a decreased conscious state, severe upper gastrointestinal bleeding, haemodynamic instability, facial trauma or surgery, inability to protect the airway and clear secretions and high risk of aspiration.[111]

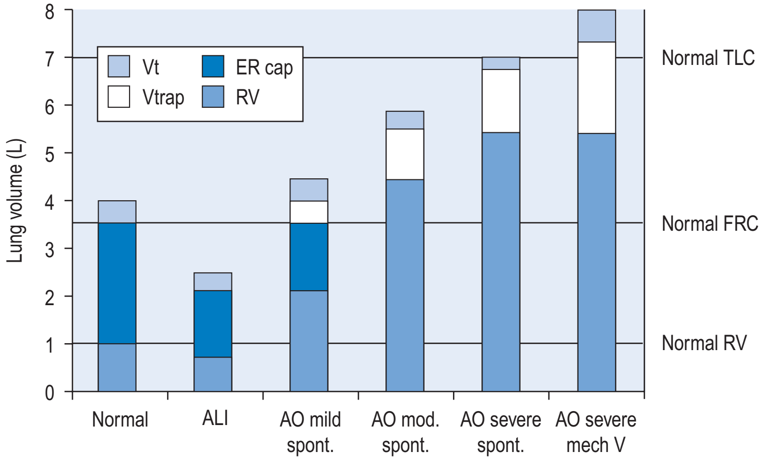

Figure 35.3 Comparison of lung volumes in patients with normal lungs, acute lung injury (ALI), and mild, moderate and severe air-flow obstruction (AO). Severe AO is shown during both spontaneous ventilation (Spont) and mechanical ventilation (Mech V). TLC=total lung capacity. Functional residual capacity (FRC) is the static lung volume at the end of expiratory flow (60-90 seconds in severe AO). Expiratory reserve capacity (ER Cap) is the additional gas expired with expiratory effort after FRC has been reached. Residual volume (RV) is the minimum lung volume possible after prolonged expiration and maximum expiratory effort. V_{trap} is the gas trapped by dynamic hyperinflation during tidal ventilation.

Nasal masks are usually not suitable in acute respiratory failure and facemasks of full-face masks fitted to achieve comfort and a reliable seal are usually best.

NIV should be commenced with 5 cmH_2O CPAP (expiratory positive airway pressure, EPAP 5 cmH_2O) and 8–10 cmH_2O pressure support (inspiratory positive airway pressure IPAP 13–15 cmH_2O). The aim is a respiratory rate <25 breaths/minute and an exhaled tidal volume of 7 mL/kg. CPAP may be increased to 7 or 10 cmH_2O if there is difficulty initiating inspiration, or pressure support may be increased if tidal volume is low or respiratory rate remains high. It is not possible to reliably achieve total pressures (IPAP) >20 cmH_2O. NIV should be undertaken in an area familiar with its use and where close observation is available.

Complications of NIV include nasal bridge ulceration, mask discomfort, nasal congestion, gastric insufflation, aspiration, hypotension and pneumothorax.[112] However, hypotension and pneumothorax are uncommon compared with their risk during mechanical ventilation.

INVASIVE VENTILATION

Invasive mechanical ventilation in acute severe asthma may be life saving, but can be associated with significant morbidity and mortality[108] (**Table 35.2**). Institution of invasive ventilation with endotracheal intubation carries the risk of inadvertent pulmonary hyperinflation[105,106,108] and potential aggravation of bronchospasm and a significant part of the morbidity and mortality has been attributed to pulmonary hyperinflation.[105,106,108] Despite these risks, the incidence of mechanical ventilation for asthma is decreasing and mortality of patients ventilated for asthma is also decreasing in some series[10,11] (see Fig. 35.1, Table 35.2).

The decision to intubate depends on both the clinical status of the patient and the natural history of the type of asthma present. Hyperacute asthma may present with marked hypercapnia (Pa_{CO_2} > 60 mmHg (7.98 kPa)) due to mechanical limitations of ventilation as a result of dynamic hyperinflation. Such patients may not initially be fatigued and may respond rapidly to treatment, thereby avoiding mechanical ventilation. Acute severe asthma that has been progressing for days may have less hypercapnia but will often respond poorly to treatment. The Pa_{CO_2} may rise despite maximal treatment owing to fatigue and the patient may require intubation at a lower Pa_{CO_2}. The general principles are to use NIV early but to avoid mechanical ventilation if safe to do so.

The decision to intubate is based primarily on the degree of respiratory distress as assessed by an experienced clinician and the patient themselves. A patient with a high Pa_{CO_2} (e.g. >70 mmHg (9.31 kPa)) who is dyspnoeic but not distressed and who may respond to full treatment over a few hours needs close observation but not immediate intubation. Patients are often able to tolerate hypercapnia without requiring invasive ventilation.[123] A patient with a lower Pa_{CO_2} (e.g. 50–60 mmHg (6.66–7.98 kPa)) who has been unwell for days, who has a deteriorating status despite treatment and significant respiratory distress is likely to need intubation. A patient who complains of respiratory exhaustion is likely to need intubation. Absolute indications for intubation include cardiac or respiratory arrest, severe hypoxia or rapid deterioration of conscious state.[17,61]

Table 35.2 Comparison of reported mortality associated with the mechanical ventilation of patients with severe asthma over the last five decades

				MORTALITY (%)		
DECADE	NO. PAPERS	NO. EPISODES	NO. DEAD	*MEAN*	*MINIMUM*	*MAXIMUM*
1960s	8	125	18	14.4	0	27
1970s	7	183	31	16.9	6	38
1980s	10	382	46	12.0	0	36
1990s	12	571	61	10.7	0	26
2000s	5	950	65	6.8	4	21

Once the decision to intubate has been made, a safe option is to perform rapid sequence intubation using the orotracheal approach. A large as possible endotracheal tube should be used to reduce the work of breathing and to reduce the risk of tube occlusion by the tenacious secretions that often occur with asthma. Once the endotracheal tube is in place, slow hand ventilation (8–10 breaths/minute) should maintain oxygenation until the ventilator can be connected.

INITIAL VENTILATOR SETTINGS

The principles of initial mechanical ventilation are avoid excessive DHI[29,105,108,109,124] and to avoid excessive hypoventilation (**Fig. 35.4**) by commencing with a minute ventilation <115 ml/kg/min (<8 L/min in a 70 kg patient) best achieved with a tidal volume of 5–7 mL/kg, a respiratory rate of 10–12 breaths/min and a short inspiratory time to ensure an expiratory time ≥4 seconds.[29,105,108,109,124] This degree of hypoventilation will usually result in hypercapnic acidosis and continued respiratory distress necessitating heavy sedation, and sometimes requires 1–2 bolus doses of a neuromuscular-blocking agent.

The use of volume-controlled ventilation is most established for this ventilatory pattern. In volume control, a high inspiratory flow rate (70–100 L/min) is required to achieve a short inspiratory time. This will result in a high peak airway pressure (PIP) but this will lower DHI and P_{plat} and reduce barotrauma compared with lower inspiratory flow rates[105,108] Pressure-controlled or assisted modes have been used[125] without adverse consequences. The theoretical advantage of a safe pressure limit in pressure modes is offset by the fact that equilibrium with the set safe pressure cannot be reached during the short inspiratory times required and thus either a higher pressure must be set or more than necessary hypoventilation may occur. It is not clear whether one mode is superior to the other.

If significant hypotension occurs this should be treated by reducing the respiratory rate, (thereby reducing dynamic hyperinflation) and volume loading.

PEEP

The role of extrinsic PEEP during mechanical ventilation of the patient with severe asthma requires careful consideration. During spontaneous breathing, CPAP has been shown to reduce facilitate the initiation of the next breath and reduce the work of breathing in many patients with severe air-flow obstruction. However, during initial controlled hypoventilation when there is an excessive level of PEEPi and dynamic hyperinflation and work of breathing is not an issue, early work has shown that extrinsic PEEP will further increase lung volumes. As this conferred no benefit and risk of detriment it was recommended that extrinsic PEEP should not be used.[109]More recently some research has suggested that low-level PEEP may improve the distribution of ventilation (as does hyperinflation) and reduce Pa_{CO_2}[126] and one study[127] has found that extrinsic PEEP may paradoxically reduce hyperinflation in some patients ventilated with air-flow obstruction. The uncertain benefit and unpredictable responses to PEEP in these latter studies continue to suggest that extrinsic PEEP should not be routinely used during controlled ventilation for severe air-flow obstruction.[126]

ASSESSMENT OF DYNAMIC HYPERINFLATION

Once mechanical ventilation has started, the degree of DHI should be assessed by measurement of *plateau airway pressure* (P_{plat}). This is the airway pressure after transient expiratory occlusion at the end of inspiration. This may be achieved by an end-inspiratory hold function on most current ventilators, which delays the commencement of the next breath (Fig. 35.4a), or by applying a 0.5 s 'plateau', which does not delay the onset of the next breath. The latter should be applied for a single breath only as application for several breaths in a row will decrease expiratory time and progressively increase DHI. This is the most easily measured estimate of average alveolar pressure at the end of inspiration and is directly proportional to the degree of hyperinflation and should be maintained at <25 cmH_2O.[105,108]

In patients with severe asthma, P_{plat} of 25 cmH2O correlated with an average end-inspiratory lung volume of <20 mL/kg (1.4 L in a 70 kg patient, Figs 35.2 and 35.3) above FRC. This has been shown to be a good predictor of complications during mechanical ventilation[108] and to correlate with a total lung volume at total lung capacity.[29]

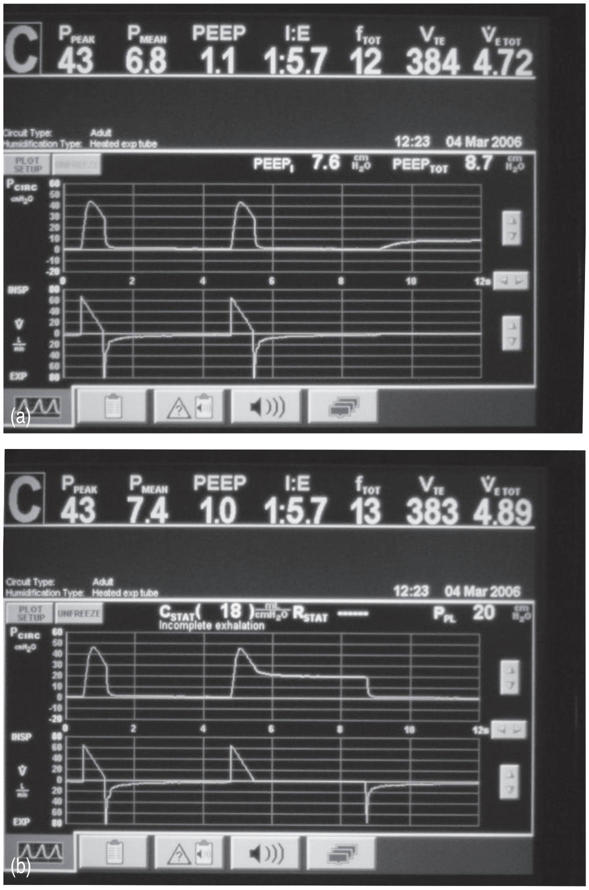

Figure 35.4 (a) The ventilator circuit pressure and flow traces versus time during controlled ventilation of a patient with severe air-flow obstruction. Note the use of a low rate, low V_t, a high inspiratory flow rate (V_i 80 L/min) and hence a short inspiratory time (t_e < 1 second). This causes a high peak airway pressure but allows a long expiratory time (>4 seconds). Expiratory flow is low throughout expiration and appears close to baseline at the onset of the next breath (2nd on screen). Suggesting minimal gas trapping but when a PEEP$_i$ manoeuvre is done (end-expiratory pause) these is a surprising degree of PEEP$_i$ present (7.6 cmH2O). (b) The ventilator circuit pressure and flow traces versus time during controlled ventilation of the same patient in part a. When a P$_{plat}$ manoeuvre is done (end-inspiratory pause) the P_{plat} is safe (20 cmH2O) with this ventilator pattern despite the degree of PEEPi present. Note the low P_{plat} despite the high peak airway pressure.

Intrinsic PEEP (PEEP$_i$) is the airway pressure during occlusion of expiratory flow at the end of expiration (Fig. 35.4b). This is also an automated end-inspiratory hold function on most current ventilators. However, this measurement is known to underestimate true PEEP$_i$, as a consequence of small-airway closure during expiration resulting in many higher-pressure alveoli not communicating with the central airway at the end of expiration.[107] Because of this, PEEP$_i$ can be used to show the presence of DHI but is not recommended to regulate the mechanical ventilation. Ideally PEEP$_i$ should be <12 cmH$_2$O although the exact safe level is unknown..

Assessment of the change in blood pressure and central venous pressure should be made during a period of transient ventilator disconnection (1–2 min) or transient ventilator rate reduction (4–6 breaths/min for 2–4 min). If DHI has been suppressing circulation then a significant increase in blood pressure and reduction in central venous pressure will occur.

ADJUSTMENT OF VENTILATION

Ventilatory patterns with excessive minute ventilation risk hypotension and barotrauma and are associated with a high mortality. Use of profound hypoventilation will guarantee avoidance of these complications but usually necessitates heavy sedation and neuromuscular blockade (**Fig. 35.5**). This, in association with parenteral steroids, has a high probability of myopathy,[74,128,129] which may cause severe prolonged disability. To minimise the risk of both these complications, DHI should be carefully assessed and the minimum amount of hypoventilation used to achieve a safe level of DHI (see Fig. 35.5) in association with less sedation and minimal or no use of neuromuscular-blocking agents.

Ventilation should be adjusted based on assessment of DHI, not on Pa$_{CO_2}$ *or pH*. If P_{plat} is >25 cmH$_2$O or circulatory suppression is present, the ventilator rate should be reduced.[105,130] If P_{plat} is low, ventilation can be liberalised by increasing the ventilator rate or reducing sedation and allowing spontaneous ventilation. Hypercapnia is usually present but is well tolerated[131] and does not appear to depress cardiac function. There is no evidence of benefit from sodium bicarbonate but it may reduce acidaemia-induced respiratory distress and may be given if the pH is less than 7.1.

When air-flow obstruction improves (decreasing P_{plat} and PEEP$_i$), sedation may be decreased, ventilator rate reduced and spontaneous ventilation assisted with pressure support ventilation. Pressure support of 10–16 cmH$_2$O may be used. Once spontaneous ventilation has commenced and when DHI is no longer critical, 3–7 cmH$_2$O CPAP may be introduced to assist ventilator triggering and reduce the work of breathing.

COMPLICATIONS OF INVASIVE VENTILATION IN ASTHMA

Hypotension may be caused by sedation, DHI, pneumothoraces or arrhythmias.[105,108] Hypovolaemia may be a contributory factor but is rarely a cause. Hypotension may be mild or life threatening.[132] Hypotension due to DHI may be diagnosed by recovery of blood pressure during apnoea of 60 seconds (the 'apnoea test')[132] or by a longer period of low ventilator rate (4–6 breaths/min for 2–4 min). If this occurs, ventilation should be continued at a lower rate.

Circulatory arrest with apparent electromechanical dissociation (EMD) is a recognised complication that may

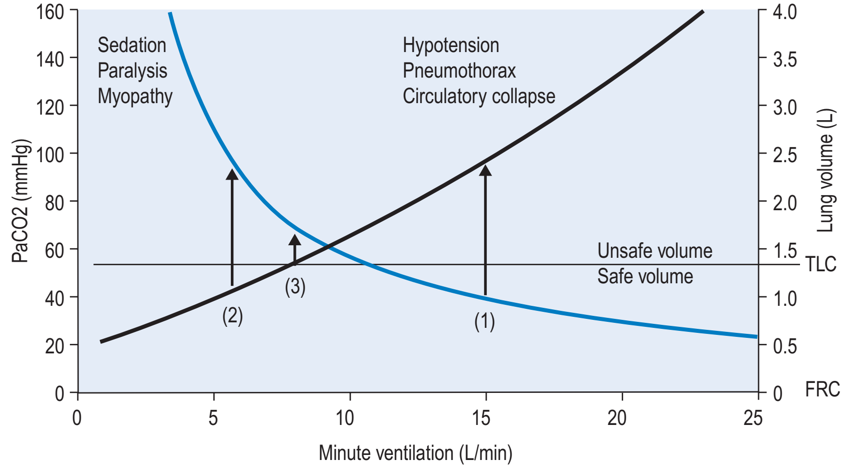

Figure 35.5 The effects of minute ventilation on Pa_{CO_2} and end-inspiratory lung volume above FRC in a typical patient with severe asthma. (1) The minute ventilation required for normocapnia, (2) profound hypoventilation, (3) optimal hypoventilation.

occur within 10 minutes of intubation and can lead to death or severe cerebral ischaemic injury if not managed correctly.[132–134] Standard mechanical ventilation recommendations (minute ventilation 115 mL/kg/min) have been estimated to be safe for 80% of patients requiring mechanical ventilation for acute severe asthma, with the remaining 20% requiring a small to moderate reduction in minute ventilation to return DHI to a safe level.[108] A small percentage of patients with unusually severe asthma can rapidly develop excessive DHI during initial uncontrolled mechanical ventilation leading to EMD, sometimes despite 'safe' levels of minute ventilation. If the cause of this is not immediately recognised, it can lead to prolonged and unnecessary CPR, unsafe procedures such as intercostal vascular access needles or pericardial taps and risk cerebral injury and death.[132–134] When this occurs, immediate disconnection from ventilation for 60–90 seconds (the 'apnoea test', above) or profound hypoventilation (2–3 breaths/min)[61] will diagnose and improve this situation. An even smaller percentage of patients may remain hypotensive despite profound hypoventilation with marked hypercapnia, fluid loading and inotropes. These patients may require heliox delivered by the mechanical ventilator[135] or extracorporeal membrane oxygenation.[134,136–138]

Pneumothoraces were common before the advent of protective ventilatory strategies. DHI during mechanical ventilation was probably the major causative factor involved.[105,108] Pneumothoraces may also occur in association with subclavian central venous catheter insertion and as a consequence of intercostal needle insertion for suspected tension pneumothorax during circulatory arrest (above). Asthma continues to remain one of the three most common conditions (with ARDS and interstitial lung disease) associated with barotrauma during mechanical ventilation with a risk rate of 6.3% compared with an overall risk rate of 2.9% for all mechanically ventilated patients.[139] The presence of severe air-flow obstruction prevents lung collapse and favours gas loss through the ruptured alveoli, with the result that tension is almost always present in the pneumothorax. Once a unilateral tension pneumothorax is present, this will necessarily reduce ventilation to that lung and redistribute ventilation to the contralateral lung thereby further increasing DHI in the second lung and bilateral tension pneumothoraces may result with severe adverse consequences.

As soon as a tension pneumothorax is suspected, the ventilator rate should be immediately reduced to decrease the risk to the second lung. Clinical diagnosis of a tension pneumothorax can be difficult as the lungs in severe asthma are already overexpanded and hyper-resonant with poor air entry. An urgent chest X-ray is always advisable for confirmation prior to intercostal catheter insertion unless severe hypotension is present. Intercostal catheters should always be inserted by blunt dissection. If intercostal needles are inserted for suspected pneumothorax, an intercostal catheter should always be inserted soon thereafter because if a tension pneumothorax was not present it is highly likely after the intercostal needles.

Acute necrotising myopathy is a serious complication that may occur in patients who are invasively ventilated for asthma and receive neuromuscular-blocking agents or very deep sedation.[74,128,129,140,141] It is characterised by weakness with electromyographic evidence of myopathy and increased serum creatine kinase levels. Muscle biopsy reveals two patterns: myonecrosis with muscle cell vacuolisation or predominant type II fibre atrophy.[74,140] Recovery can be slow with prolonged weaning from mechanical ventilation, the need for rehabilitation. Incomplete recovery after 12 months has been reported in a few patients.[141,142] The aetiology of the myopathy appears to be a combination of the effects of corticosteroids and neuromuscular-blocking agents (NMBA) with the duration of paralysis a strong predictor of myopathy.[141,142] The type of NMBA used seems to

Box 35.1 Key points

1. Asthma prevalence in the community is increasing but admissions to hospital and intensive care are decreasing
2. Acute severe asthma is a life-threatening medical emergency both on presentation and during mechanical ventilation
3. Underestimation of severity and under-treatment are the biggest contributors to asthma mortality
4. Patients who do require mechanical ventilation have more severe asthma refractory to treatment and are more difficult to ventilate
5. Intravenous and continuous nebulised salbutamol can cause significant lactic acidosis
6. Mechanical ventilation can easily cause excessive dynamic hyperinflation leading to hypotension and pneumothorax
7. Mechanical ventilation needs careful regulation with initial $V_e < 115$ mL/kg/min (8 L/min) and $P_{plat} < 25$ mmHg (3.32 kPa)
8. Very severe dynamic hyperinflation can lead to cardiorespiratory collapse diagnosed by an apnoea test
9. Neuromuscular-blocking agents and heavy sedation can lead to severe necrotising myopathy
10. Following intensive care, asthma requires full treatment including inhaled steroids, a management plan and careful follow-up.

make no difference to the incidence of myopathy.[140] Effective paralysis by deep sedation without the use of NMBAs also confers the risk of severe weakness in this patient group.[143] Gehlbach et al[15] found that the risk factors for prolonged mechanical ventilation were female gender, use of NMBAs, requirement for inhaled corticosteroids prior to admission and a high illness severity score (APACHE II). The relative contributions of corticosteroids versus NMBAs in the causation of myopathy are unclear. It seems wise to minimise the dose of parenteral corticosteroids with early introduction of nebulised agents, to minimise or avoid NMBAs if possible and minimise deep sedation.

MORTALITY, LONG-TERM OUTCOME AND FOLLOW-UP

In a summary of 37 papers reporting the outcomes of 1260 patients requiring mechanical ventilation for asthma in the four decades prior to the year 2000,[62] there was an overall mortality of 12.4% with a progressive reduction in reported mortality during that period (see Table 35.2). A selection of reports[10,12,14,15,21] published since 2000 have shown continued reduction in overall mortality (see Table 35.2) but with mortalities as high as 21% still occurring in one series.[14] The largest and most comprehensive recent series[10] reported 1899 patients admitted to 22 Australian intensive care units over an 8-year period (1996–2003). This series reported a requirement for mechanical ventilation for 36% of patients admitted with severe asthma and a progressive reduction in annual mortality of the ventilated patients from 10% to 3% over the 8-year period.

The need for invasive ventilation increases the risk of death[10,14,144] and survivors of these near-fatal episodes of asthma have an increased risk of intensive care re-admission and an increased risk of death after hospital discharge.[33,34] For these reasons, patients who have an episode of asthma severe enough to require hospitalisation, particularly intensive care admission, need careful follow-up. This should include active identification and avoidance of precipitants, aggressive bronchodilator therapy including inhaled steroids, regular medical review, regular measurement of lung function, management plans for a deteriorating status, and ready access to emergency services. Patients with difficult asthma may benefit from detailed psychological and sometimes speech therapy assessment.[18]

Pneumonia

Kai Man Chan and Charles D Gomersall

The management of pneumonia is based on four findings and premises:

- Pneumonia is associated with a wide range of largely non-specific clinical features.[1]
- Pneumonia can be caused by over 100 organisms.
- The relationship between specific clinical features and aetiological organism is insufficiently strong to allow a clinical diagnosis of the causative organism.[2]
- Early administration of appropriate antibiotics is important.[2]

The net result is that the differential diagnosis is wide and treatment should be started before the aetiological agent is known. The differential diagnosis and the likely causative organisms can be narrowed by using epidemiological clues, the most important of which are whether the pneumonia is community-acquired or healthcare-associated and whether the patient is immunocompromised. Note that the flora and antibiotic resistance patterns vary from country to country, hospital to hospital and even ICU to ICU within a hospital and this must be taken into account.

COMMUNITY-ACQUIRED PNEUMONIA

Evidence-based guidelines have been issued by the British Thoracic Society,[3] the Infectious Diseases Society of America (IDSA) and American Thoracic Society (ATS)[2] and the European Respiratory Society.[4] Links to these and other pneumonia-related guidelines can be found at the following 'link page': http://www.aic.cuhk.edu.hk/web8/Pneumonia%20guidelines.htm.

DEFINITION

An acute infection of the pulmonary parenchyma that is associated with at least some symptoms of acute infection, accompanied by an acute infiltrate on a chest radiograph (CXR), or auscultatory findings consistent with pneumonia (e.g. altered breath sounds, localised crackles) in a patient not hospitalised or residing in a long-term care facility for ≥14 days prior to the onset of symptoms.

The overall incidence is 3–40 per 1000 inhabitants per year, with 40–60% requiring hospital admission. Overall, 10% of patients are admitted to ICU. The overall mortality of hospitalised patient is approximately 10%.[5]

AETIOLOGY

Table 36.1 gives possible aetiological agents based on epidemiological clues. *Streptococcus pneumoniae* is the most commonly isolated organism. The next most common bacterial pathogens in patients admitted to ICU are: *Legionella* species, *Haemophilus influenzae,* Enterobacteriaceae species, *Staphylococcus aureus* and *Pseudomonas* species.[2]

CLINICAL PRESENTATION

Pneumonia produces both systemic and respiratory manifestations. Common clinical findings include fever, sweats, rigors, cough, sputum production, pleuritic chest pain, dyspnoea, tachypnoea, pleural rub and inspiratory crackles. Classic signs of consolidation occur in less than 25% of cases. Multi-organ dysfunction or failure may occur depending on the type and severity of pneumonia.

The diagnosis of pneumonia may be more difficult in the elderly. Although the vast majority of elderly patients with pneumonia have respiratory symptoms and signs, over 50% may also have non-respiratory symptoms and over a third may have no systemic signs of infection.

INVESTIGATIONS[2,4]

Investigations should not delay administration of antibiotics as delays are associated with an increase in mortality.[2] Important investigations include:

1. Chest X-ray (CXR)
2. Arterial blood gases or oximetry
3. Full blood count
4. Serum creatinine, urea and electrolytes
5. Liver function tests
6. Blood cultures (×2) prior to the administration of antimicrobials
7. Sputum (if immediately available) for urgent Gram stain and culture. The usefulness of sputum tests remains debatable because of contamination by upper respiratory tract commensals. However, a

Table 36.1 Possible aetiological agents based on epidemiological clues[2,3,9,7]

EXPOSURE	ORGANISM
EXPOSURE TO ANIMALS	
Handling turkeys, chickens, ducks or psittacine birds or their excreta	*Chlamydia psittaci*
Exposure to birds in countries in which avian flu has been identified in birds	Influenza A H5N1
Handling infected parturient cats, cattle, goats or sheep or their hides	*Coxiella burneti*
Handling infected wool	*Bacillus anthracis*
Handling infected cattle, pigs, goats or sheep or their milk	*Brucella* spp.
Insect bite. Transmission from rodents and wild animals (e.g. rabbits) to laboratory workers, farmers and hunters	*Francisella tularensis*
Insect bites or scratches; transmission from infected rodents or cats to laboratory workers and hunters	*Yersinia pestis*
Contact with infected horses (very rare)	*Pseudomonas mallei*
Exposure to mice or mice droppings	Hantavirus
GEOGRAPHICAL FACTORS	
Immigration from or residence in countries with high prevalence of TB	*Mycobacterium tuberculosis*
North America; contact with infected bats or birds or their excreta; excavation in endemic areas	*Histoplasma capsulatum*
South-west USA	*Coccidiodes* species, Hantavirus
USA; inhalation of spores from soil	*Blastomyces dermatitidis*
Asia, Pacific, Caribbean, north Australia. Contact with local animals or contaminated skin abrasions	*Burkholderia pseudomallei*
HOST FACTORS	
Diabetic ketoacidosis	*Streptococcus pneumoniae, Staphylococcus aureus*
Alcoholism	*Strep. pneumoniae, S. aureus, Klebsiella pneumoniae*, oral anaerobes, *M. tuberculosis, Acinetobacter* spp.
Chronic obstructive pulmonary disease or smoking	*Strep. pneumoniae, Haemophilus influenzae, Moraxella catarrhalis, Chlamydia pneumoniae, Legionella* spp., *Pseudomonas aeruginosa*
Sickle cell disease	*Strep. pneumoniae*
Pneumonia complicating whooping cough	*Bordatella pertussis*
Pneumonia complicating influenza	*Strep. pneumoniae, S. aureus*, CA-MRSA
Pneumonia severe enough to necessitate artificial ventilation	*Strep. pneumoniae, Legionella* spp., *S. aureus, Haemophilus influenzae, Mycoplasma pneumoniae*, enteric Gram-negative bacilli, *Chlamydia pneumoniae, M. tuberculosis*, viral infection, endemic fungi
Nursing home residency	Treat as healthcare-associated pneumonia
Poor dental hygiene	Anaerobes
Suspected large-volume aspiration	Oral anaerobes, Gram-negative enteric bacteria
Structural disease of lung (e.g. bronchiectasis, cystic fibrosis)	*P. aeruginosa, Burkholderia cepacia, S. aureus*

Table 36.1 Possible aetiological agents based on epidemiological clues—cont'd

EXPOSURE	ORGANISM
Lung abscess	Community-acquired meticillin-resistant *S. aureus*, oral anaerobes, endemic fungi, *M. tuberculosis*, atypical mycobacteria
Endobronchial obstruction	Anaerobes, *Strep. pneumoniae, H. influenzae, S. aureus*
Intravenous drug addict	*S. aureus*, CA-MRSA, anaerobes, *M. tuberculosis, Strep. pneumoniae*
End-stage renal failure	CA-MRSA
OTHERS	
Epidemic	*M. pneumoniae,* influenza virus
Air-conditioning cooling towers, hot tubs or hotel or cruise ship stay in previous 2 weeks	*Legionella pneumophilia*
Presentation of a cluster of cases over a very short period of time	Bioterrorist agents: *B. anthracis, F. tularensis, Y. pestis*

single or predominant organism on a Gram stain of a fresh sample or a heavy growth on culture of purulent sputum is likely to be the organism responsible. The finding of many polymorphonuclear cells (PMN) with no bacteria in a patient who has not already received antibiotics can reliably exclude infection by most ordinary bacterial pathogens. Specimens should be obtained by deep cough and be grossly purulent. Ideally the specimen should be obtained before treatment with antimicrobials, if this does not delay administration of antibiotics, and be transported to the laboratory immediately for prompt processing to minimise the chance of missing fastidious organisms (e.g. *Strep. pneumoniae*). Acceptable specimens (in patients with normal or raised white blood cell counts) should contain >25 PMN per low-power field (LPF) and <10–25 squamous epithelial cells (SEC)/LPF or >10 PMN per SEC. These criteria should not be used for *Mycobacteria* and *Legionella* infection. Certain organisms are virtually always pathogens when recovered from respiratory secretions (**Box 36.1**). Patients with risk factors for tuberculosis (TB) (**Box 36.2**), and particularly those with cough for more than a month, other common symptoms of TB and suggestive radiographic changes, should have sputum examined for acid-fast bacilli. Sputum cannot be processed for culture for anaerobes owing to contamination by the endogenous anaerobic flora of the upper respiratory tract. In addition to the factors listed in Table 36.1, foul-smelling sputum, lung abscess and empyema should raise suspicion of anaerobic infection.

8. Aspiration of pleural fluid for Gram stain, culture, pH and leucocyte count – all patients with a pleural effusion >1 cm thick on a lateral decubitus chest X-ray.

Box 36.1 Organisms that are virtually always pathogens when recovered from respiratory secretions

Legionella
Chlamydia
TB
Influenza, para-influenza virus, RSV, adenovirus, hantavirus, SARS coronavirus
Stronglyloides stercoralis
Toxoplasma gondi
Histoplasma capsulatum
Coccidiodes immitis
Blastomycoses dermatitidis
Cryptococcus neoformans

Box 36.2 Risk factors for pulmonary tuberculosis

Living in or originating from a developing country
Age (<5 years, middle-aged and elderly men)
Alcoholism and/or drug addiction
HIV infection
Diabetes mellitus
Lodging-house dwellers
Immunosuppression
Close contact with smear-positive patients
Silicosis
Poverty and/or malnutrition
Previous gastrectomy
Smoking

9. Urinary *Legionella* antigen. This test is specific (>95%). In patients with severe Legionnaires disease sensitivity is 88–100% for *L. pneumophilia* serogroup 1 (the most commonly reported cause of *Legionella* infection). Thus a positive result is virtually

diagnostic of *Legionella* infection but a negative result does not exclude it. In areas (e.g. South Australia) where other *Legionella* species are more common, this test is less helpful.

10. Urinary pneumococcal antigen has moderate sensitivity (50–80%) and high specificity (>90%).
11. Microimmunofluorescence serology for *Chlamydia pneumoniae* IgM. A titre ≥1:16 is significant.
12. HIV serological status.

Other investigations should be considered in patients with risk factors for infection with unusual organisms. Bronchoalveolar lavage may be useful in immunocompromised patients, those who fail to respond to antibiotics, or those in whom sputum samples cannot be obtained.[6]

Molecular diagnosis (e.g. PCR-based methods) has the advantages of quick results (within 3 hours), enhanced sensitivity, independence from organism viability and hence previous antibiotics, and theoretical possibility for determination of antimicrobial susceptibility.[7] Of note, it is important to test for genes specific for the organism in question[10] and the sampling site remains important. PCR is most useful when performed on specimens from a normally sterile site. For example, PCR for *Pneumococcus* is positive in 62% of blood samples from adult patients with confirmed or probable pneumococcal pneumonia,[8] whereas blood cultures are positive in only 37%. For respiratory specimens under most circumstances, interpretation remains problematic due to low specificity related to floral contamination and colonisation. PCR assays are more sensitive than culture for *Mycoplasma* and *Chlamydia* species and at least as sensitive for *Legionella*.[7] PCR assays also detect *Legionella* strains other than serogroup 1. The BTS guidelines[3] recommend PCR of lower respiratory tract sample or, if unavailable, throat swab for the diagnosis of *Mycoplasma* pneumonia. PCR for *Chlamydophilia* should be performed when invasive respiratory samples were collected from patients with severe community-acquired pneumonia. The role of PCR in diagnosing PCP is mainly limited to non-HIV patients, in whom conventional microscopy and staining of induced sputum and BAL have a lower sensitivity than in HIV patients.[9]

MANAGEMENT

GENERAL SUPPORTIVE MEASURES

Intravenous fluids may be required to correct dehydration and provide maintenance fluid. A general approach should be made to organ support with an emphasis on correcting hypoxia.

ANTIMICROBIAL REGIMENS

Increased mortality among those who do not receive empirical antibiotics that cover the infecting pathogen(s) is well documented.[11] Each unit should have its own regimens tailored to the local flora and antibiotic resistance patterns. In the absence of such regimens the regimen outlined in **Figure 36.1** may be helpful. This

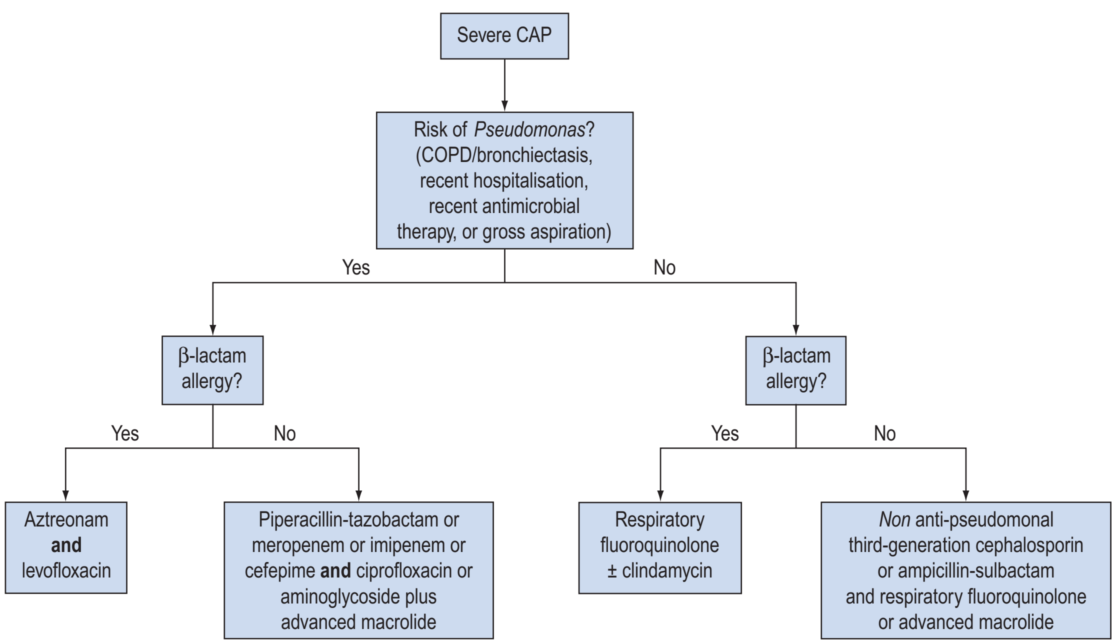

Figure 36.1 Antibiotic regimens for treatment of severe community-acquired pneumonia in critically ill patients.[2,4] Respiratory fluoroquinolones include moxifloxacin and levofloxacin. Advanced macrolides include azithromycin and clarithromycin. Non-antipseudomonal third-generation cephalosporins include cefotaxime and ceftriaxone.

should be modified in the light of risk factors (see Table 36.1). Quinolones may be less appropriate in areas with a high prevalence of TB as their use may mask concurrent TB infection. Appropriate antimicrobial therapy should be administered within 1 hour of diagnosis.[4,12] There is controversy regarding the appropriate change to empirical therapy based on microbiological findings.[2,4] Changing to narrower-spectrum antimicrobial cover may result in inadequate treatment of the 5–38% of patients with polymicrobial infection. Increasing evidence demonstrates improved outcome with combination antimicrobial as compared with monotherapy, particularly in severely ill patients with bacteraemic pneumococcal pneumonia.[5] Odds ratio of death was 1.5 to 6 for monotherapy as compared with combination therapy. Benefits were seen only in combination therapy with macrolide as part of the regimen, but not in combination with fluroquinolone regimen.[13] For the treatment of drug-resistant *Strep. pneumoniae* (DRSP) the regimens in Figure 36.1 are probably suitable for isolates with a penicillin MIC<4 mg/L.[2] If the MIC is ≥4 mg/L an antipneumococcal fluoroquinolone, vancomycin, teicoplanin or linezolid should be given.[4]

DURATION OF THERAPY

No clinical trial has specifically addressed this issue. Courses as short as 5 days may be sufficient.[14] IDSA/ATS guidelines recommend stopping after a minimum of 5 days if the patient is afebrile for 48–72 hours and organ dysfunction has largely resolved.[2] Short courses may be suboptimal for patients with bacteraemic *S. aureus* pneumonia, meningitis or endocarditis complicating pneumonia or infection with less common organisms (e.g. *Burkholderia pseudomallei* or fungi) or *Pseudomonas aeruginosa*. Procalcitonin may be useful to guide antibiotic therapy, but not all studies have demonstrated a benefit.[15]

RESPONSE TO THERAPY[2]

This can be assessed subjectively (a response is usually seen within 1–3 days of starting therapy) or objectively on the basis of respiratory symptoms, fever, oxygenation, WBC count, bacteriology, CXR changes, C-reactive protein reduction and procalcitonin reduction of 80–90% from peak value. The average time to defervescence varies with organism, severity and patient age (7 days in elderly patients, 2.5 days in young patients with pneumococcal pneumonia, 6–7 days in bacteraemic patients with pneumococcal pneumonia, 1–2 days in patients with *M. pneumoniae* pneumonia and 5 days in patients with *Legionella* pneumonia). Both blood and sputum cultures are usually negative within 24–48 hours of treatment although *P. aeruginosa* and *M. pneumoniae* may persist in the sputum despite effective therapy. CXR changes lag behind clinical changes with the speed of change depending on the organism, the age of the patient and the presence or absence of comorbid illnesses. The CXR of most young or middle-aged patients with bacteraemic pneumococcal pneumonia is clear by 4 weeks, but resolution is slower in elderly patients and patients with underlying illness, extensive pneumonia on presentation or *Legionella pneumophilia* pneumonia.

If the patient fails to respond consider the following questions:

- Has the patient got pneumonia?
- Are there host factors that explain the failure (e.g. obstruction of bronchus by a foreign body or tumour, inadequate host response)?
- Has a complication developed (e.g. empyema, superinfection, bronchiolitis obliterans organising pneumonia, metastatic abscess)?
- Is the right drug being given in an adequate dose by the right route?
- Is the organism resistant to the drug being given?
- Are there other organisms?
- Is the fever a drug fever?

Useful investigations include computerised tomography (CT) of the chest, thoracocentesis, bronchoalveolar lavage (**Table 36.2**) and transbronchial or open-lung biopsy.

PREDICTION OF ADVERSE OUTCOME AND ADMISSION TO ICU

Scoring systems have been developed to predict adverse outcome and ICU admission including pneumonia severity index (PSI), CURB-65, CRB-65, modified ATS major and minor criteria, SCAP prediction rule, SMART-COP, REA-ICU index and CAP-PIRO.[16] Although they may help identify the sicker patients they should not be used as a sole determinant of ICU admission as local admission criteria will be affected by local facilities, both in and outside ICU. It should be noted that none of the criteria has been prospectively demonstrated to avoid late transfers or lower mortality.

INFLUENZA PNEUMONIA

Influenza pneumonia may present with severe respiratory failure and multi-organ failure. However the pattern of organ failure appears to vary between strains with H5N1 being associated with a much higher mortality and a higher incidence of multi-organ failure than pandemic H1N1,[17] which itself presented differently to seasonal influenza. In particular, trophism for lower respiratory tract, a higher rate of ICU admission[18] and a higher rate of extrapulmonary complications[19] were observed.

Early initiation of oseltamivir is recommended for critically ill patients although there is no direct evidence of outcome benefit. Glucocorticoids do not appear to be useful and may prolong viral replication.[20] Bacterial superinfection should be considered, with Gram-positive cocci being most frequently isolated.[21]

Table 36.2 Procedure for obtaining microbiological samples using bronchoscopy and protected specimen brushing and/or bronchoalveolar lavage[35,49]

Infection control	In patients suspected of having a disease that is transmitted by the airborne route (e.g. tuberculosis): • the risk of transmission should be carefully weighed against the benefits of bronchoscopy, which may generate large numbers of airborne particles • perform bronchoscopy in a negative-pressure isolation room • consider the use of a muscle relaxant in ventilated patients, to prevent coughing • staff should wear personal protective equipment, which should include a fit-tested negative-pressure respirator (N95, FFP2 or above) as a minimum; use of a powered air-purifying respirator should be considered
General recommendations	Suction through the endotracheal tube should be performed before bronchoscopy Avoid suction or injection through the working channel of the bronchoscope Perform protected specimen brushing before bronchoalveolar lavage
Ventilated patients	Set Fi_{O_2} at 1.0 Set peak pressure alarm at a level that allows adequate ventilation Titrate ventilator settings against exhaled tidal volume Consider neuromuscular blockade in addition to sedation in patients at high risk of complications who are undergoing prolonged bronchoscopy
Protected specimen brushing (PSB)	Sample the consolidated segment of lung at subsegmental level If purulent secretions are not seen advance the brush until it can no longer be seen, but avoid wedging it in a peripheral position Move brush back and forth and rotate it several times
Bronchoalveolar lavage (BAL)	Wedge tip of bronchoscope into a subsegment of the consolidated segment of lung Inject, aspirate and collect 20 mL of sterile isotonic saline. Do not use this sample for quantitative microbiology or identification of intracellular organisms. It can be used for other microbiological analysis Inject, aspirate and collect additional aliquots of 20–60 mL The total volume of saline injected should be 60–200 mL
Complications	Hypoxaemia (possibly less with smaller BAL volumes) Arrhythmia Transient worsening in pulmonary infiltrates Bleeding (particularly following PSB) Fever (more common after BAL)
Positive results	>5% of cells in cytocentrifuge preparations of BAL fluid contain intracellular bacteria OR $\geq 10^3$ colony-forming units/mL in PSB specimen OR $\geq 10^4$ colony-forming units/mL in BAL fluid

Although there are data demonstrating that surgical masks are as effective as N95 (FFP 2) masks in preventing transmission of seasonal influenza in non-ICU settings it is important to note that the capacity for airborne transmission (and hence the need for N95 masks) is dependent on the exact characteristics of the organism and the frequency of aerosol-generating procedures so these data should not be extrapolated to other influenza viruses and ICU settings.

HEALTHCARE-ASSOCIATED PNEUMONIA

Nosocomial pneumonia occurs in 0.5–5% of hospital patients, with a higher incidence in certain groups (e.g. postoperative patients and patients in ICU). Diagnosis may be difficult: the clinical features of pneumonia are non-specific and many non-infectious conditions (e.g. atelectasis, pulmonary embolus, aspiration, heart failure and cancer) can cause infiltrates on a chest X-ray. Identification of the organism responsible is even more difficult than in patients with community-acquired pneumonia owing to the high incidence of oropharyngeal colonisation by Gram-negative bacteria. Blood cultures are positive in only about 6% of cases of nosocomial pneumonia. Ventilator-associated pneumonia (VAP) is nosocomial pneumonia arising >48–72 hours after intubation. Reported incidence of VAP is between 10 and 20% for those receiving mechanical ventilation for more than 48 hours.[22] It is associated with a higher incidence of multi-drug-resistant organisms.[1]

PATHOGENESIS

Nosocomial pneumonia is thought to result from microaspiration of bacteria colonising the upper respiratory tract. Other routes of infection include macroaspiration

of gastric contents, inhaled aerosols, haematogenous spread, spread from pleural space and direct inoculation from ICU personnel.

CLINICAL DIAGNOSIS

Diagnosis is based on time of onset (>48 hours after admission to a healthcare facility[1]), CXR changes (new or progressive infiltrates) and either clinical features and simple laboratory investigations or the results of quantitative microbiology. Using a clinical approach, pneumonia is diagnosed by the finding of a new infiltrate or a change in an infiltrate on chest radiograph and growth of pathogenic organisms from sputum plus one of the following: white-blood-cell (WBC) count greater than 12×10^5/L, core temperature ≥38.3°C, sputum Gram stain with scores of more than two on a scale of four of polymorphonuclear leucocytes and bacteria.

INVESTIGATIONS

These are broadly similar to those required in community-acquired pneumonia:

- *Chest X-ray:* although studies using a histological diagnosis as the gold standard have demonstrated that pneumonia may be present despite a normal CXR, most definitions of nosocomial pneumonia require the presence of new persistent infiltrates on a CXR.
- *Respiratory secretions:* considerable controversy surrounds the issue of whether invasive bronchoscopic sampling (Table 36.2) of respiratory secretions is necessary. Whether invasive sampling is employed or tracheal aspirates are used, empirical broad-spectrum antibiotics should be started while results are awaited. The results of microbiological analysis of respiratory secretions are used to either stop antibiotics or narrow the spectrum.[1] Although the use of an invasive strategy is associated with a higher likelihood of modification of initial antimicrobials,[23] the effect on important clinical outcome such as mortality, antibiotic-free days, and organ dysfunction is variable.[1] Although tracheal aspirates may predominantly reflect the organisms colonising the upper airway, they may be useful in indicating which organisms are not responsible for the pneumonia, thus allowing the antimicrobial cover to be narrowed.[1] This interpretation is based on the premise that the predominant route of infection is via the upper respiratory tract. From this it can be assumed that if the organism is not present in the upper respiratory tract the probability of it being present in the lung parenchyma is low. Certain organisms are virtually always pathogens when recovered from respiratory secretions (see Box 36.1).
- *Blood cultures:* identify the aetiological agent in 8–20% of patients. Bacteraemia is associated with a worse prognosis. In 50% of patients with severe hospital-acquired pneumonia and positive blood cultures there is another source of sepsis.

MANAGEMENT

Management is based on the finding that early treatment with antimicrobials that cover all likely pathogens results in a reduction in morbidity and mortality.[2] The initial selection of antimicrobials is made on the basis of epidemiological clues (**Fig. 36.2**, **Table 36.3**). Antimicrobials should be administered within 1 hour of diagnosis.[12] The results of microbiological investigations are used to narrow antimicrobial cover later. Treatment should be reassessed after 2–3 days or sooner if the patient deteriorates (**Fig. 36.3**). An outline of management based on an invasive approach is given in **Figure 36.4**.

DURATION OF THERAPY

Current ATS guidelines recommend 7 days' treatment provided the aetiological agent is not *P. aeruginosa* or other non-lactose fermenter and the patient has a good clinical response with resolution of clinical features of infection.[1] The outcome of patients who receive appropriate initial empirical therapy for ventilator-associated pneumonia for 8 days is similar to those who receive treatment for 15 days.[1]

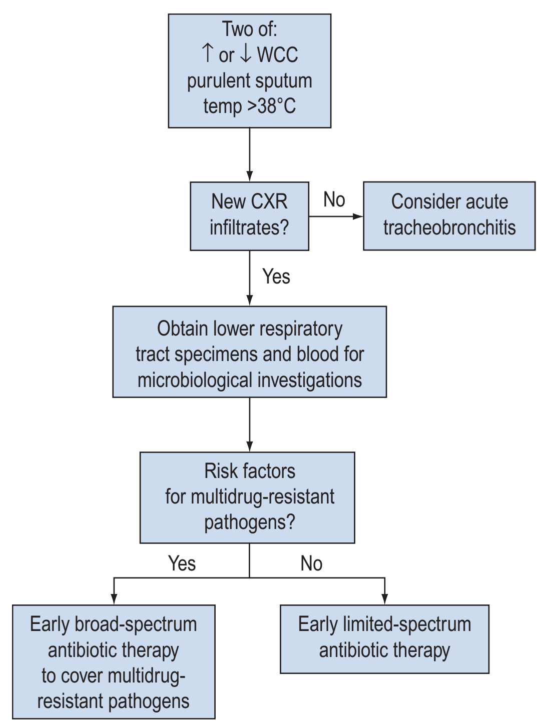

Figure 36.2 An outline of initial management of nosocomial pneumonia based on a non-invasive clinical approach.[1]

Table 36.3 Recommended initial empirical treatment for nosocomial pneumonia[1]

SITUATION	ANTIBIOTICS
No risk factors for multidrug-resistant pathogens	Ceftriaxone *or* Levofloxacin, moxifloxacin or ciprofloxacin *or* Ampicillin/sulbactam *or* Ertapenem
Antimicrobial therapy in previous 90 days *or* Current hospitalization for ≥5 days *or* High frequency of antibiotic resistance in the specific hospital unit *or* Hospitalisation for 2 days or more in previous 90 days *or* Residence in nursing home or extended care facility *or* Home infusion therapy (including antibiotics) *or* Chronic dialysis within 30 days *or* Home wound care *or* Family member with multidrug-resistant pathogen *or* Immunosuppression *or* Bronchiectasis	One of: Antipseudomonal cephalosporin (cefepime or ceftazidime) *or* Antipseudomonal carbapenem (meropenem or imipenem–cilastin) *or* ß-lactam/ß-lactamase inhibitor (e.g. piperacillin–tazobactam *or* cefaperazone–sulbactam) *plus* one of: Aminoglycoside *or* Antipseudomonal quinolone (levofloxacin or ciprofloxacin) *plus* one of the following for patients at high risk of meticillin-resistant *Staphylococcus aureus* (MRSA) infection: Linezolid *or* Vancomycin *or* Teicoplanin

The use of dual therapy is not well supported by evidence but it does reduce the probability that the pathogen is resistant to the drugs being given. If an extended spectrum β-lactamase-producing strain or an *Acinetobacter* sp. is suspected a carbapenem should be given. If *Legionella pneumophilia* is suspected use a quinolone. Risk factors for MRSA infection in areas with a high incidence of MRSA include diabetes mellitus, head trauma, coma and renal failure.

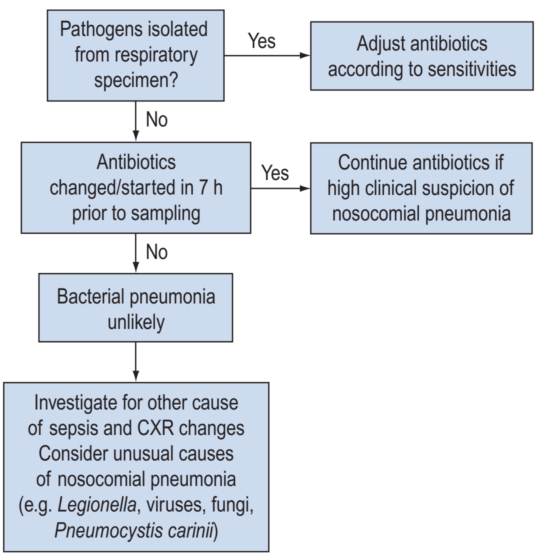

Figure 36.3 Subsequent management of nosocomial pneumonia based on a non-invasive clinical approach.[1]

RESPONSE TO THERAPY

Clinical improvement is usually not apparent for 48–72 hours and therapy should not be changed during this time. The CXR is of limited value for assessing response; initial deterioration is common and improvement often lags behind clinical response. However, a rapidly deteriorating CXR pattern with a >50% increase in size of infiltrate in 48 hours, new cavitation or a significant new pleural effusion should raise concern. If the patient fails to respond consider the diagnosis, host factors (e.g. immunosuppressed, debilitated), bacterial factors (e.g. virulent organism) and therapeutic factors (e.g. wrong drug, inadequate dose). Review the antibiotics and repeat cultures. It may be useful to broaden the antimicrobial cover while waiting for the results of investigations. Consider invasive sampling of respiratory secretions, computerised tomography or ultrasound of the chest (to look for an empyema or abscess), another source of infection, open-lung biopsy to establish diagnosis and aetiology, or administration of steroids.

MORTALITY AND MORBIDITY ATTRIBUTABLE TO VAP

Substantial morbidity and mortality associated with VAP have previously been reported.[22] However, a causal relationship is difficult to establish. It should be noted that patients who developed VAP tend to be more severely ill and at higher risk of death not only on ICU admission, but throughout the course of their illness. Most of the relevant studies were observational and failed to adequately control confounders like disease severity, evolution of disease progression, and ICU length of stay with mortality. In addition, significant heterogeneity exists among these studies. Although the presence of VAP is associated with a significantly longer ICU length of stay (mean of 6.1 days; 95% CI: 5.32–6.87) and increased healthcare cost,[22] more recent studies reported that mortality attributable to VAP tends to be small, if any.[24,25] The attributable mortality has been reported to be 1% on the 30th day of ICU and

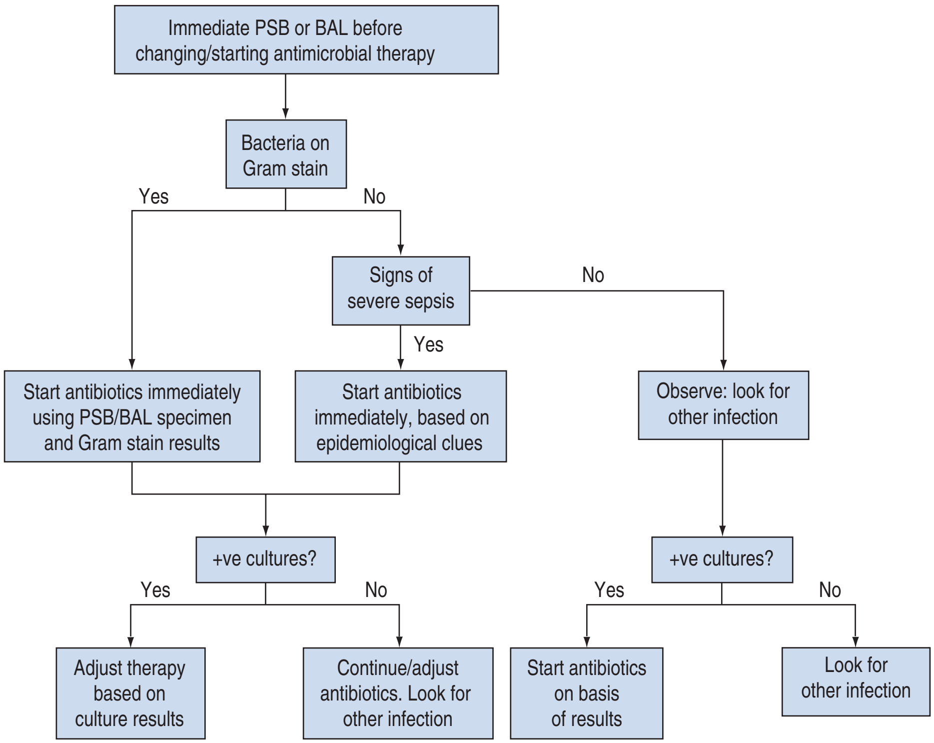

Figure 36.4 Management of suspected nosocomial pneumonia based on invasive sampling of respiratory secretions.

1.5% on the 60th day of ICU in a recent study using a multicentre high-quality database and incorporating novel statistical methodology to control evolution of severity of illness.[25]

PREVENTION

Several guidelines for prevention of ventilator-associated pneumonia and hospital-acquired pneumonia have been published.[26–30] Interventions can be divided into general infection control measures and specific measures. General measures include alcohol-based hand disinfection, hospital education programme on infection control, the use of microbiological surveillance and a programme to reduce antibiotic prescription. The major specific recommendations are summarised in **Table 36.4**. There is no evidence that 'bundles' of recommendations are more effective than the sum of the individual components.

TUBERCULOSIS

The main risk factors are listed in Box 36.2. Typical clinical features include fever, sweating, weight loss, lassitude, anorexia, cough productive of mucoid or purulent sputum, haemoptysis, chest wall pain, dyspnoea, localised wheeze and apical crackles. Patients may also present with unresolved pneumonia, pleural effusions, spontaneous pneumothorax and hoarseness or with enlarged cervical nodes or other manifestations of extrapulmonary disease. Clinical disease is seldom found in asymptomatic individuals, even those with strongly positive tuberculin test (Heaf grade III or IV). The outlook for patients with tuberculosis who require ICU admission is poor. In one retrospective study the in-hospital mortality for all patients with tuberculosis requiring ICU admission was 67% but in those with acute respiratory failure it rose to 81%.[31] The presentation and management of TB in HIV-positive patients are different (see below).

INVESTIGATION OF PULMONARY TUBERCULOSIS

IDENTIFICATION OF MYCOBACTERIA

Multiple[32,33] sputum samples should be collected, preferably on different days, for microscopy for acid-fast bacilli and culture. If sputum is not available bronchial washings taken at bronchoscopy and gastric lavage or aspirate samples should be obtained. Gastric aspirates need to be neutralised immediately on collection. Bronchoscopy and transbronchial biopsy may be useful in patients with suspected TB but negative sputum smear. Pleural biopsy is often helpful and mediastinoscopy is occasionally needed in patients with mediastinal lymphadenopathy. Part of any biopsy specimen should always be sent for culture. Nucleic acid amplification tests on sputum have sensitivity similar to culture in

Table 36.4 Strategies for prevention of ventilator-associated pneumonia

LEVELS OF RECOMMENDATIONS	SPECIFIC INTERVENTIONS	REMARKS
Universally recommended by all guidelines[27–30]	1. Semirecumbent position to 45°	At least 30–45°
	2. Avoidance of endotracheal intubation	
	3. Preference of oral tracheal route	
	4. New circuit for a new patient and no schedule change unless soiled or damaged	
	5. Avoidance of flushing of condensate into lower airway or in-line medication	
	6. HME changes no more frequently than 5–7 days	
	7. Continuous aspiration of subglottic suctioning	For patients expected to require mechanical ventilation for >72 hours
Generally recommended by most guidelines	1. Preferential use of non-invasive ventilation[27,28,30]	
	2. Avoidance of unplanned re-intubation[27,28,30]	
	3. Maintenance of endotracheal cuff pressure of about 20 mmHg (2.66 kPa)[27,28,30]	
	4. Closed suctioning[28,29]	No effect on VAP, mainly for staff safety
	5. Chlorhexidine oral decontamination[27,29,30]	
	6. Sedation vacation and weaning protocol[27,28]	
	7. Judicious use of stress ulcer prophylaxis[27,28,30]	
	8. Restrictive blood transfusion[28]	
Benefits less clear	1. Preference of HME over heated humidifier[28,30]	HME associated with reduction in VAP in patients ventilated for >7 days, lower cost
	2. Silver-sulfadiazine-coated endotracheal tube[27,28,30]	
	3. Early tracheostomy (within 7 days of mechanical ventilation)[29]	
	4. Selective decontamination of digestive tract (SDD)[27,28,30]	Mortality reduction demonstrated when topical antimicrobials combined with short-course systemic antibiotics, BSAC recommended SDD in patients expected to require mechanical ventilation for >48 hours, ETF discourage routine use due to concern of emergence of resistant organisms
Not yet reviewed by guidelines[50]	1. High-volume low-pressure ultrathin membrane endotracheal tube cuff with SSD	
	2. Ultrathin membrane cuff with tapered shape and SSD	
	3. Low-volume low-pressure endotracheal tube cuff with SSD	
	4. Balloon device for biofilm removal	
	5. Saline instillation before tracheal suctioning	

HME=heat moist exchanger; SSD=subglottic secretion drainage.

smear-negative patients with pulmonary tuberculosis but have the advantage of a much more rapid result. There is, however, a significant false-negative rate.[32]

CHEST X-RAY (CXR)

A normal CXR almost excludes TB (except in HIV-infected patients) but endobronchial lesions may not be apparent and early apical lesions can be missed. Common appearances include patchy/nodular shadowing in the upper zones (often bilateral), cavitation, calcification, hilar or mediastinal lymphadenopathy (may cause segmental or lobar collapse), pleural effusion, tuberculomas (dense round or oval shadows) and diffuse fine nodular shadowing throughout the lung fields in miliary TB. Inactivity of disease cannot be inferred from the CXR alone. This requires three negative sputum samples *and* failure of any lesion seen on CXR to progress. CXR appearances in HIV-positive

patients with TB differ from those in non-HIV-infected patients.

TREATMENT OF PULMONARY TB[32–34]

The decision to initiate anti-TB treatment should be based on level of clinical suspicion, results of AFB smear and sometimes mycobacterial culture. If the initial clinical suspicion is strong and the patient is seriously ill attributable to possible TB, treatment should be initiated promptly, sometimes before the result of AFB smear. Subsequent positivity of AFB smear or nucleic acid amplification test provides support to the continuation of treatment. Combination chemotherapy consisting of four drugs is necessary for maximal efficacy. Treatment is divided into initial phase and continuation phase. The most commonly used initial regimen consists of 8 weeks of rifampicin 600 mg daily (450 mg for patients <50 kg), isoniazid 300 mg daily, pyrazinamide 2 g daily (1.5 g for patients <50 kg) and ethambutol 15 mg/kg daily as initial phase treatment. Ethambutol should be used only in patients who have reasonable visual acuity and who are able to appreciate and report visual disturbances. This mandates careful consideration in patients who require heavy sedation. Visual acuity and colour perception must be assessed (if ethambutol is to be used) and liver and renal function checked before treatment is started. Steroids are recommended for children with endobronchial disease and, possibly, for patients with tuberculous pleural effusions. Pyridoxine 10 mg daily should be given to prevent isoniazid-induced neuropathy to those at increased risk (e.g. patients with diabetes mellitus, chronic renal failure or malnutrition or alcoholic or HIV-positive patients). Negative AFB smear should not delay initial treatment if clinical suspicion remains high. Supporting features included chronic cough, weight loss, characteristic chest X-ray findings, emigration from a high-incidence country, no other immediate diagnosis, and positive tuberculin test.

INFECTION CONTROL

Patients admitted to an ICU with infectious TB or suspected of having active pulmonary TB should be managed in an isolation room with special ventilation characteristics, including negative pressure. Patients should be considered infectious if they are coughing or undergoing cough-inducing procedures or if they have positive AFB smears and they are not on or have just started chemotherapy, or have a poor clinical or bacteriological response to chemotherapy.[32,35] Patients with non-drug-resistant TB should be non-infectious after 2 weeks of treatment which includes rifampicin and isoniazid.[32] As TB spreads through aerosols it is probably appropriate to isolate patients who are intubated even if only their bronchial washings are smear-positive. Staff caring for patients who are smear-positive should wear personal protective equipment including a fit-tested negative-pressure respirator (N95, FFP2 or higher). Use of a powered air-purifying respirator should be considered when bronchoscopy is being performed.[35] Detailed infection control advice can be obtained via the 'link page' (http://www.aic.cuhk.edu.hk/web8/Pneumonia%20guidelines.htm.).

PNEUMONIA IN THE IMMUNOCOMPROMISED

The lungs are amongst the most frequent target organs for infectious complications in the immunocompromised. The incidence of pneumonia is highest amongst patients with haematological malignancies, bone marrow transplant (BMT) recipients and patients with AIDS.

The speed of progression of pneumonia, the CXR changes (**Table 36.5**) and the type of immune defect provide clues to the aetiology. Bacterial pneumonias progress rapidly (1–2 days) whereas fungal and protozoal pneumonias are less fulminant (several days to a week or more). Viral pneumonias are usually not fulminant, but on occasions may develop quite rapidly. Bronchoscopy is a major component of the investigation of these patients. Empirical management based on CXR appearances is outlined in Table 36.5. Early non-invasive ventilation may improve outcome amongst immunocompromised patients with fever and bilateral infiltrates.[36]

PNEUMOCYSTIS JIROVECI PNEUMONIA (PCP)[37]

The incidence of this common opportunistic infection has fallen substantially in patients with AIDS who are receiving prophylaxis and effective antiretroviral therapy, with most cases occurring in patients who are not receiving HIV care or among patients with advanced immunosuppression. The onset is usually insidious with dry cough, dyspnoea and fever on a background of fatigue and weight loss. Crackles in the chest are rare. Approximately 15% of patients have a concurrent cause for respiratory failure (e.g. Kaposi sarcoma, TB, bacterial pneumonia). Useful investigations are:

1. *CXR:* classical appearance is diffuse bilateral perihilar interstitial shadowing, but in the early stages this is very subtle and easily missed. The initial CXR is normal in 10%. In a further 10% the changes are atypical with focal consolidation or coarse patchy shadowing. None of the changes are specific for PCP and may be seen in other lung diseases associated with AIDS. Pleural effusions, hilar or mediastinal lymphadenopathy are unusual in PCP but common in mycobacterial infection or Kaposi's sarcoma or lymphoma.
2. *Induced sputum:* in this technique the patient inhales nebulised hypertonic saline from an ultrasonic nebuliser. This provokes bronchorrhoea and the patient

Table 36.5 Causes of CXR changes and empirical treatment of pneumonia in the immunocompromised

CHEST X-RAY APPEARANCE	CAUSES	EMPIRICAL TREATMENT FOR SUSPECTED PNEUMONIA
Diffuse infiltrate	CMV and other herpes viruses *Pneumocystis carinii* Bacteria *Aspergillus* (advanced) *Cryptococcus* (uncommon) Non-infectious causes, e.g. drug reaction, non-specific interstitial pneumonitis, radiation pneumonitis (uncommon), malignancy, leucoagglutinin reaction	Broad-spectrum antibiotics for at least 48 h (e.g. 3rd-generation cephalosporin and aminoglycoside) Co-trimoxazole Lung biopsy or lavage within 48 h or full 2-week course of co-trimoxazole (depends on patient tolerance of invasive procedure)
Focal infiltrate	Gram-negative rods *S. aureus* *Aspergillus* *Cryptococcus* *Nocardia* *Mucor.* *P. carinii* (uncommon) Tuberculosis Legionella Non-infectious causes (e.g. malignancy, non-specific interstitial pneumonitis, radiation pneumonitis)	Broad-spectrum antibiotics If response seen continue treatment for 2 weeks If disease progresses lung biopsy/aspirate within 48–72 hours or empirical trial of antifungal ± macrolide

coughs up material containing cysts and trophozoites. The technique is time-consuming and requires meticulous technique and is less sensitive than bronchoscopy but less invasive. The possibility of concurrent tuberculosis should be considered and steps taken to minimise the risk of spread of infection.

3. Bronchoscopy with bronchoalveolar lavage leads to the diagnosis in over 90% of cases. Specimens should be sent for cytology. Transbronchial biopsy is not necessary in most cases. PCR using bronchial lavage specimens may be useful in non-HIV patients with suspected PCP.

Antipneumocystis treatment should be started as soon as the diagnosis is suspected. Treatment of choice is trimethoprim plus sulfamethoxazole (co-trimoxazole) 20 mg/kg/day + 100 mg/kg/day for 3 weeks plus prednisolone 40 mg orally twice daily for 5 days followed by 20 mg twice daily for 5 days and then 20 mg per day until the end of PCP treatment. Side-effects of co-trimoxazole are common in HIV patients (nausea, vomiting, skin rash, myelotoxicity). The dose should be reduced by 25% if the WBC count falls. Patients who are intolerant of co-trimoxazole should be treated with:

- pentamidine 4 mg/kg/day i.v. or
- primaquine with clindamycin or
- trimetrexate with leucovorin (±oral dapsone).

Response to treatment is usually excellent, with a response time of 4–7 days. If the patient deteriorates or fails to improve: consider (re-)bronchoscopy (is the diagnosis correct?), treat co-pathogens and consider a short course of high-dose i.v. methylprednisolone and/or diuretics (patients often fluid-overloaded). Approximately 40% of patients with HIV-related PCP who require mechanical ventilation survive to hospital discharge.[38]

Initiation of antiretroviral therapy in patients presenting with HIV-related PCP is controversial. The Centers for Disease Control and Prevention (CDC) recommend against doing so in the acute phase, but recent data suggest that the outcome may be improved by initiation within the first 4 days of ICU admission.[39]

BACTERIAL PNEUMONIA[37]

This is the most common cause of acute respiratory failure in HIV-positive patients. Bacterial pneumonia is more common in HIV-infected patients than in the general population and tends to be more severe. *Strep. pneumoniae, H. influenza, Pseudomonas aeruginosa* and *S. aureus* are the commonest organisms. *Nocardia* and Gram negatives should also be considered. Atypical pathogens (e.g. *Legionella*) are rare. Response to appropriate antibiotics is usually good but may require protracted courses of antibiotics because of high tendency to relapse. Patients with severe immunodeficiency ($CD4^+$ T lymphocyte count <100/μL) and a history of *Pseudomonas* infection or bronchiectasis or neutropenia should receive antibiotics that cover *P. aeruginosa* as well as other Gram negatives. The possibility of concurrent PCP or tuberculosis should be excluded.

TUBERCULOSIS

TB may be the initial presentation of AIDS, particularly in sub-Saharan Africa. The pattern of TB in HIV patients

depends on the degree of immunosuppression. In patients with CD4+ T lymphocytes >350 cells/μL the clinical presentation is similar to TB in non-HIV-infected patients, although extrapulmonary disease is more common. In patients with CD4+ T lymphocytes <350 cells/μL extrapulmonary disease (pleuritis, pericarditis, meningitis) is common. Severely immunocompromised patients (CD4+ T lymphocytes <100 cells/μL) may present with severe systemic disease with high fever, rapid progression and systemic sepsis. In these patients lower and middle lobe disease is more common, miliary disease is common and cavitation is less common. Sputum smears and culture may be positive even with a normal CXR.

Response to treatment is usually rapid. Management of TB in HIV is complex owing to numerous drug interactions; consultation with an expert in treatment of HIV-related TB should be strongly considered. Complex interactions occur between rifamycins (e.g. rifampicin and rifabutin) and protease inhibitors and non-nucleoside reverse transcriptase inhibitors used to treat patients infected with HIV. The choice of rifampicin or rifabutin depends on a number of factors including the unique and synergistic adverse effects for each individual combination of rifampicin and anti-HIV drugs, and consultation with a physician with experience in treating both TB and HIV is advised.[40] IDSA-recommended dosage adjustment for patients receiving antiretrovirals and rifabutin[37] can be obtained via the 'link page' (http://www.aic.cuhk.edu.hk/web8/Pneumonia%20guidelines.htm.). The optimal time for initiating antiretroviral therapy in patients with TB is controversial. Early therapy may decrease HIV disease progression but may be associated with a high incidence of adverse effects and an immune reconstitution reaction.[37]

CMV PNEUMONITIS[41,42]

Risk of infection is highest following allogeneic stem cell transplantation, followed by lung transplantation, pancreas transplantation and then liver, heart and renal transplantation and advanced AIDS. If both the recipient and the donor are seronegative then the risk of both infection and disease are negligible. If the recipient is seropositive the risk of infection is approximately 70% but the risk of disease is only 20%, regardless of the serostatus of the donor. However if the recipient is seronegative and the donor is seropositive the risk of disease is 70%. If steroid pulses and antilymphocyte globulin are given for treatment of acute rejection the risk of developing disease is markedly increased. Infection may be the result of primary infection or reactivation of latent infection. It is clinically important, but often difficult to distinguish between CMV infection and CMV disease and a definitive diagnosis can be made only histologically. Detection of CMV-pp65 antigen in peripheral WBC and detection of CMV DNA or RNA in the blood by quantitative polymerase chain reaction are the most useful tests for demonstrating CMV disease. Using thresholds of 10/300 000–50/200 000 positive circulating peripheral WBC, the positive predictive value for CMV-pp65 ranges from 64% to 82% and the negative predictive value from 70% to 95%[43,44] Treatment consists of intravenous ganciclovir for at least 14 days. Foscarnet can be used if ganciclovir fails.

FUNGAL PNEUMONIA

Fungi are rare but important causes of pneumonia. They can be divided into two main groups based on the immune response required to combat infection with these organisms. Histoplasma, blastomycosis, coccidioidomycosis, paracoccidioidomycosis and *Cryptococcus* require specific cell-mediated immunity for their control and thus, in contrast to infections that are controlled by phagocytic activity, the diseases caused by these organisms can occur in otherwise healthy individuals although they cause much more severe illness in patients with impaired cell-mediated immunity (e.g. patients infected with HIV and organ transplant recipients). With the exception of *Cryptococcus* these organisms are rarely seen outside North America. *Aspergillus* and *Mucor* spores are killed by non-immune phagocytes and as a result these fungi rarely result in clinical illness in patients with normal neutrophil numbers and function.

CANDIDIASIS

This is effectively a combination of the two types of fungal infection in which impaired cell-mediated immunity predisposes to mucosal overgrowth with *Candida* but impaired phagocytic function or numbers is usually required before deep invasion of tissues occurs. Primary *Candida* pneumonia (i.e. isolated lung infection) is uncommon[41,45] and more commonly pulmonary lesions are only one manifestation of disseminated candidiasis. Even more common is benign colonisation of the airway with *Candida*. In most reported cases of primary *Candida* pneumonia amphotericin B has been used. In disseminated candidiasis treatment should be directed to treatment of disseminated disease rather than *Candida* pneumonia per se.[45]

INVASIVE ASPERGILLOSIS[46]

This is a highly lethal condition in the immunocompromised despite treatment and therefore investigation and treatment should be prompt and aggressive. It is associated with exposure to construction work. Definitive diagnosis requires both histological evidence of acute-angle branching, septated non-pigmented hyphae measuring 2–4 μm in width, and cultures yielding *Aspergillus* species from biopsy specimens of involved organs. Recovery of *Aspergillus* species from respiratory secretions in immunocompromised, but not immunocompetent, patients may indicate invasive disease with a positive predictive value as high as

80–90% in patients with leukaemia or bone marrow transplant recipients. Bronchoalveolar lavage with smear, culture and antigen detection has excellent specificity and reasonably good positive predictive value for invasive aspergillosis in immunocompromised patients. Although radiological features may give a clue to the diagnosis they are not sufficiently specific to be diagnostic.

In acutely ill immunocompromised patients intravenous therapy should be initiated if there is suggestive evidence of invasive aspergillosis while further investigations to confirm or refute the diagnosis are carried out. First-line therapy is voriconazole.[47] Echinocandins and amphotericin are alternatives.

PARAPNEUMONIC EFFUSION

This may be an uncomplicated effusion that resolves with appropriate treatment of the underlying pneumonia or a complicated effusion that develops into an empyema unless drained. Complicated effusions tend to develop 7–14 days after initial fluid formation. They are characterised by increasing pleural fluid volume, continued fever and pleural fluid of low pH (<7.3) that contains a large number of neutrophils and may reveal organisms on Gram staining or culture. An outline of management is given in **Figure 36.5**.

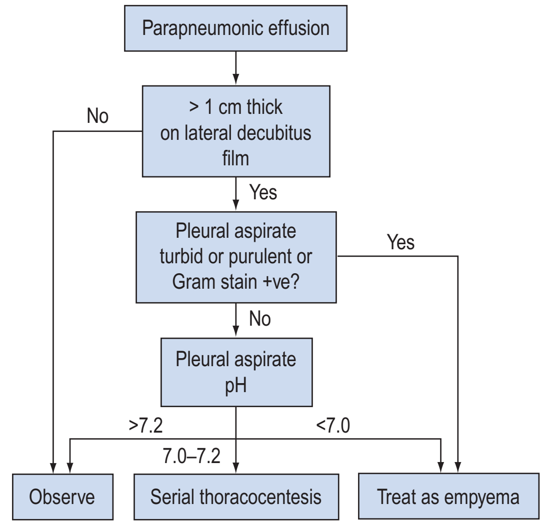

Figure 36.5 An approach to the management of parapneumonic effusions.

EMPYEMA[48]

DEFINITION

Collection of pus in the pleural space.

AETIOLOGY

Follows infection of the structures surrounding the pleural space, including subdiaphragmatic structures, and chest trauma, or may be associated with malignancy. Anaerobic bacteria, usually streptococci or Gram-negative rods, are responsible for 76% of cases.

DIAGNOSIS

The diagnosis is usually simple. The patient is usually septic and may have a productive cough and chest pain. The chest X-ray may show features suggestive of a pleural effusion and underlying consolidation but may also show an abscess cavity with a fluid level, in which case CT scanning will be required to distinguish between an abscess and an empyema. Ultrasound can be useful to confirm the presence of fluid in the pleural space and to determine whether it can be drained by needle aspiration or, if there is debris within the fluid, drainage using an intercostal drain. The diagnosis is confirmed by aspiration of pus.

TREATMENT

The mainstay of treatment is drainage either by intercostal drain or by surgical intervention. Patients who present before the pus is loculated and a fibrinous peel has formed on the lung can usually be treated by simple drainage. The combination with intrapleural fibrinolysis may be beneficial. Optimal surgical management, which consists of decortication (open or thoracoscopic), is indicated if the empyema is more advanced or if simple drainage fails. This is a major procedure and many patients with cardiac or chronic respiratory disease will not tolerate it. Alternatives for these patients are instillation of thrombolytics into the pleural space or thoracostomy. Antibiotics have only an adjunctive role. Broad-spectrum antibiotic regimens with anaerobic cover should be used until the results of microbiological analysis of the aspirated pus are available.

Non-invasive ventilation

Graeme J Duke and Andrew D Bersten

Non-invasive ventilation (NIV) is a valuable therapeutic option in the management of acute and chronic respiratory failure – for certain diagnoses it is the preferred option. The application of NIV predates the introduction of laryngoscopy (early 1900s) and the widespread use of positive-pressure mechanical ventilation via an endotracheal tube (MV) in the 1950s.[1] Successful use of NIV in acute respiratory failure was first published in 1936.[2]

NIV is defined as ventilatory support without an (invasive) endotracheal airway. It has an increasingly important role in the early management of reversible acute respiratory failure (ARF),[3,4] and in domicilary management of chronic respiratory failure due to obstructive sleep apnoea (OSA) and neuromuscular disease.

NIV may be achieved either through the delivery of positive pressure to the airway (P_{ao}) or the application of a negative-pressure generator to the chest ('chest box' or cuirass) or body ('iron lung'). A conceptual framework is shown in **Figure 37.1**.

Negative-pressure generators may be used for the management of acute or chronic respiratory disease.[5] Major limitations to the use of negative-pressure generators include the induction of OSA, lack of fractional inspired oxygen (Fi_{O_2}) control, equipment bulk and size.[6] However, external negative-pressure generators suit some patients with chronic respiratory failure, particularly as there is no oral or nasal prosthesis. This chapter deals primarily with the use of positive-pressure NIV to treat ARF.

The clinical efficacy of NIV depends upon: (a) the mode used and (b) the nature and severity of the underlying respiratory pathophysiology. Correctly applied, NIV can reduce morbidity and mortality, whereas inappropriate application may delay definitive therapy and adversely affect outcome. An understanding of the physiological rationale for NIV will assist the clinician understand the indications and benefits, and predict the side-effects of the various NIV modes.[7,8] Several important aspects regarding ventilatory support are discussed in Chapter 31 (Mechanical ventilation), and this chapter will focus on those aspects specific to NIV.

PHYSIOLOGY OF NIV

The physiological benefits of NIV are similar to those of invasive ventilatory support. NIV can reverse many of the adverse physiological and mechanical derangements associated with ARF, through a combination of:

- augmentation of alveolar ventilation (V_A) to reverse respiratory acidosis and hypercarbia
- alveolar recruitment and increased Fi_{O_2} to reverse hypoxia
- reduction in work of breathing (W_{mus}) to reduce or prevent respiratory muscle insufficiency
- stabilisation of the chest wall in the presence of chest trauma or surgery
- reduction in left ventricular (LV) afterload that may lead to improved cardiac function
- reduction of right ventricular afterload and improved right ventricular function.[9]

In brief, the respiratory effort (pressure–volume work) required to achieve a desired minute volume (V_E) may be viewed as the summation of the individual forces that must be overcome to generate inspiratory flow, namely: elastic work (or 'stretch'; W_{el}), flow-resistive work (air-flow obstruction; W_{res}) and threshold work. Threshold work, the work required to overcome the effects of dynamic hyperinflation and intrinsic PEEP ($PEEP_i$) prior to triggering inspiratory assistance, is another form of elastic work and included as part of W_{el}. Since the volume component is constant the equation of motion can be written as:

$$P_{mus} = P_{el} + P_{res} \quad (37.1)$$

(See Ch. 31, Mechanical ventilation, for more detailed explanation.)

With the addition of a device for ventilatory support, the respiratory muscle effort (P_{mus}) required by the patient is equivalent to the difference between the applied P_{ao} and the total work required to maintain V_E:

$$P_{mus} = (P_{el} + P_{res}) - P_{ao} \quad (37.2)$$

This relationship may be rearranged into its individual components, as follows:

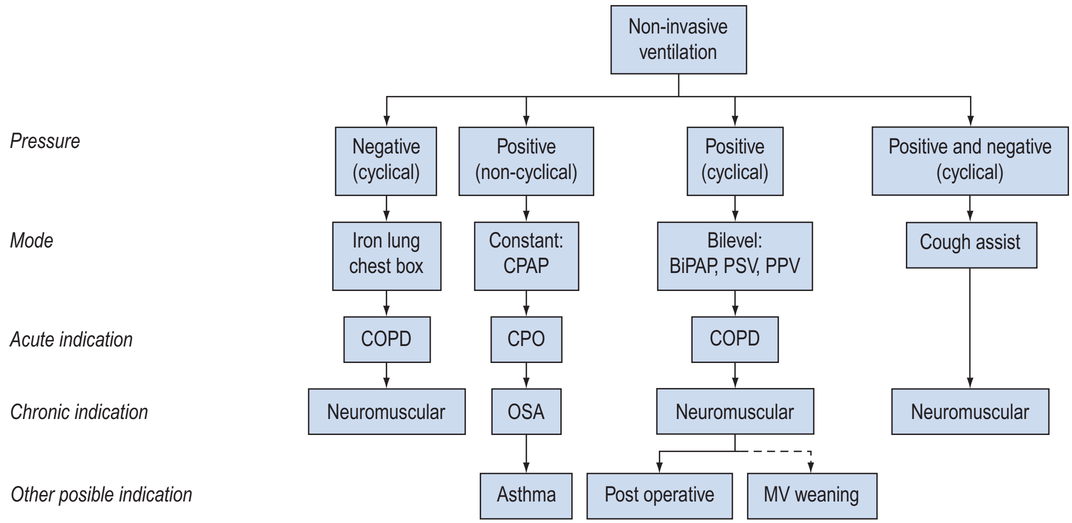

Figure 37.1 Conceptual NIV paradigm. (See text for definitions.)

$$P_{mus} + P_{ao} = E \bullet V + R \bullet \dot{V} + \mathrm{PEEP_i} \quad (37.3)$$

where E is the respiratory elastance (inverse of compliance), V is the volume of gas, R is the respiratory and circuit flow resistance, $\dot{V}$ is the inspiratory flow rate and $\mathrm{PEEP_i}$ is the intrinsic PEEP

It is important to remember that breathing via a circuit will create additional air-flow resistance (R) adding to breathing work (P_{mus}), and thus attention to circuit design is important (see below).

$\mathrm{PEEP_i}$ and dynamic hyperinflation are absent in the healthy lung, but common in the presence of tachypnoea and/or expiratory air-flow obstruction. During flow limitation, $\mathrm{PEEP_i}$ impedes the onset (triggering) of inspiratory support modes (IPAP and PSV). This threshold load ($\mathrm{PEEP_i}$) must be counterbalanced by either an equivalent amount of inspiratory effort or end-expiratory pressure before inspiratory flow can commence.

Respiratory failure occurs when the forces opposing inspiration – namely elastic (P_{el}), resistive (P_{res}) and threshold ($\mathrm{PEEP_i}$) work – exceed the respiratory muscle effort (P_{mus}) required to maintain V_E. Hypermetabolic states (e.g. trauma, sepsis) increase basal V_E, whereas pulmonary and chest wall diseases increase respiratory workload and neuromuscular disease impairs respiratory muscle effort. NIV may prevent respiratory failure by counterbalancing the increased respiratory workload and/or reducing respiratory muscle effort, and thus maintain V_A.

Any invasive MV mode may be delivered non-invasively and four are commonly described in clinical research: continuous positive airway pressure (CPAP), PSV, bilevel or biphasic positive airway pressure (BIPAP), and pressure- or volume-limited intermittent positive-pressure ventilation. Other modes under investigation include high-frequency and proportional assist ventilation.

All NIV modalities utilise (semi-closed or) closed circuits and are thus capable of controlling and delivering high Fi_{O_2}. This is an important mechanism by which NIV improves oxygenation, independently of other mechanisms discussed below.

CONTINUOUS POSITIVE AIRWAY PRESSURE

CPAP is a form of NIV because it provides respiratory support even though the P_{ao} applied is constant throughout the respiratory cycle. This mode addresses a number of the objectives of ventilatory support, namely:

- reduction in the work of breathing by:
  - alveolar recruitment and reduction in elastic work
  - reducing threshold load created in the presence of $\mathrm{PEEP_i}$
- reversing hypoxia through delivery of high Fi_{O_2}, alveolar recruitment, and reduction of intrapulmonary shunt
- reduction of left ventricular (LV) transmural pressure (afterload).[10,11]

INSPIRATORY POSITIVE AIRWAY PRESSURE (IPAP) AND PSV

Positive inspiratory airway pressure without expiratory pressure (e.g. PSV or IPAP), provides respiratory support by reducing both the elastic and resistive components of respiratory work resulting in:

- augmentation of tidal volume (V_E) and reduction in Pa_{CO_2}

- reduction in P_{mus} and diminish or prevent respiratory muscle insufficiency
- induction of pulmonary surfactant release through alveolar inflation above resting tidal volume.[12]

Bilevel positive airway pressure allows separate settings for inspiratory (IPAP) and expiratory (EPAP) airway pressure levels; it is conceptually similar to PSV plus CPAP.[13] Respiratory frequency is usually patient-dependent but may be mechanically time cycled and independent of patient effort.

CONTROLLED VENTILATION

NIV may also be administered as volume- or pressure-limited mechanical ventilation applied via a mask (instead of an endotracheal airway).

PATIENT–VENTILATOR INTERACTION

This is discussed in Chapter 31 (Mechanical ventilation), and subdivided into: (a) triggering of inspiration, (b) inspiration and (c) cessation of inspiration. The only aspect that is specific to NIV arises from mask leaks, which may interfere with the ability to sense the end of expiration because there is continued 'expiratory' gas flow.

NIV EQUIPMENT

Equipment design varies according to NIV mode and purpose (e.g. critical care or domiciliary setting), and significant variations in performance characteristics have been documented.[1,14] The important characteristics of an efficient NIV circuit include:

- high gas flow to match peak inspiratory air flow – high flows may be generated by a pressurised gas supply, a gas turbine, or a jet venturi mechanism: a device providing continuous flow imposes less circuit work than a demand flow device
- an expiratory resistor capable of maintaining the desired PEEP, yet offering a low resistance to expiratory flow to reduce fluctuations in the delivered P_{ao} – this may be a threshold resistor or flow resistor; the optimal position for the expiratory valve is as close to the patient's airway as possible
- short wide-bore tubing to reduce turbulence and flow resistance
- a flow or pressure sensor for identifying inspiratory effort and triggering the predetermined inspiratory pressure support (e.g. PSV or IPAP)
- ability to control and deliver a wide range of Fi_{O_2}
- other desirable features include the facility to humidify inspired gases and to nebulise drugs. the provision for pressure-relief safety valves, battery back-up, apnoea back-up support, acoustic suppression and monitoring of volume and P_{ao} are important for hospital NIV equipment and less important for domiciliary (long-term) devices.

Several varieties of mask design are also available and the optimal configuration depends upon the purpose and mode of NIV, patient anatomy, and preference. These include intranasal, nasal, and oronasal, full-face and helmet (full-head) masks. Desirable features of a mask include lightweight and transparent materials affording a comfortable airtight seal, minimal dead space, and separate inspiratory and expiratory ports to minimise air-flow turbulence and rebreathing.[14,15] In lung model studies, expiratory ports over the nasal bridge reduce dead space,[16] which may prove to be clinically advantageous, and traditional orofacial masks have lower dead space than full-face masks or helmet designs.[17]

Mask discomfort, arising from the mask seal, air leaks, humidification, or claustrophobia, is a common cause of noncompliance. Masks that cover nose and mouth tend to produce more reliable and constant P_{ao} because they are unaffected by mouth breathing – a common problem in the critically ill patient. Nasal masks are less restrictive on the patient's ability to talk, eat/drink, and expectorate and therefore gain higher compliance in long-term and domiciliary applications. To effectively compensate for air leaks, nasal masks should be used with circuits capable of rapidly augmenting and delivering high flows (>100 L/min).

Fibreoptic bronchoscopy can be safely performed during NIV, using a full-face mask with at least two ports. One of these can be modified to provide a simple valve for insertion of the bronchoscope, and the other used for NIV. Provided there is adequate flow reserve during suction, this can be performed during any mode of NIV. This technique may allow both diagnostic and therapeutic bronchoscopic intervention without intubation even in critically ill patients.

COMPLICATIONS AND ASSESSMENT OF EFFICACY

Contraindications and complications specific to NIV are listed in **Box 37.1**. Acutely unwell patients requiring NIV should be managed in a critical care ward, or similar area with appropriately trained on-site medical and nursing staff. Although the development of sophisticated, portable non-invasive ventilators makes it easy to provide NIV in any environment, its benefits may diminish outside the critical care environment.[18,19]

Following the initial application of NIV reversal of hypoxia and reduction in respiratory effort is commonly observed irrespective of the underlying disease. Although these intermediate goals are important, they are a poor guide to the efficacy of NIV. More reliable clinical measures of NIV efficacy include reversal of hypercarbia, a sustained improvement in respiratory function and patient outcomes, such as a reduction in non-compliance, intubation, nosocomial pneumonia and mortality.

Box 37.1 Contraindications and complications of NIV

Contraindications
- Respiratory arrest
- Unprotected airway (coma, sedation)
- Upper airway obstruction
- Inability to clear secretions
- Untreated pneumothorax
- Marked haemodynamic instability

Complications
- Mask discomfort, patient intolerance
- Facial or ocular abrasions
- Nasal congestion, sinus pain
- Oronasal dryness
- ↑ Intraocular pressure (particularly in patients with glaucoma)
- ↑ Intracranial pressure (particularly in patients with neurotrauma)
- ↓ Blood pressure (if hypovolaemic)
- Aspiration pneumonia (rare)
- Aerophagy and gastric distension (uncommon; routine gastric decompression is unnecessary)

NIV AND ACUTE RESPIRATORY FAILURE (ARF)

CARDIOGENIC PULMONARY OEDEMA (CPO)[1,8,21]

CPO is a common cause of severe reversible ARF. Since the 1930s, a number of investigators have documented the therapeutic benefits of all modes of NIV, particularly CPAP. CPO leads to an increase in elastic workload (P_{el}) and, to a less extent, resistive workload (P_{res}), an increase in lung water and impaired surfactant function. CPAP reverses hypoxia, recruits alveoli and reduces intrapulmonary shunt and LV afterload. Redistribution of extravascular lung water from alveoli to the interstitial space is aided by recruitment of alveoli and surfactant production.

Over 30 prospective randomised controlled trials of NIV in CPO have consistently demonstrated physiological improvements in hypoxic and hypercapnic respiratory failure, and a significant reduction in the need for intubation (95% CI RR=0.32–0.60), hospital length of stay, and improved survival (95% CI RR=0.44–0.92).[19] Even though the majority of these patients were managed in a critical care setting the average length of stay and duration of respiratory support was much shorter for NIV (9±11 hours) than those who required MV.[22]

The optimal mode of NIV in CPO appears to be CPAP. The optimal P_{ao} level remains to be resolved, although 10 cmH_2O appeared to be safe and effective in the majority of subjects. Although the addition of a differential inspiratory pressure (e.g. bilevel[23] and PSV[24,25]) may be as effective as CPAP in avoiding (95% CI RR=0.33–0.86) intubation it may not provide a survival benefit and may increase the rate of myocardial infarction[26,27] (95% CI RR=0.92–2.42).[21]

Benefits appear to be greater in those with acute coronary syndrome as the primary aetiology.[21] CPAP reduces preload and afterload[10,11] and myocardial catecholamine release[28] whereas the cyclical P_{ao} (of bilevel NIV) may cause fluctuation in preload and afterload during respiration.[1,29] Current evidence supports the routine use of mask-CPAP in moderate or severe CPO as standard therapy and as the first-line option for respiratory support.[18,30]

ARF IN CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD)

COPD patients have an elevated resistive work (P_{res}), often coupled with an elevated basal V_E and elastic work (P_{el}) as a result of the pre-existing parenchymal damage. Threshold load ($PEEP_i$) is frequently present as a result of air-flow obstruction, and is exacerbated during ARF by further increased P_{res} and respiratory rate. Reversible ARF is a common complication of COPD.

The importance of NIV in hypercapnic ARF is now supported by at least 14 well-performed prospective randomised controlled studies[20,31–33] in over 600 patients. Most investigators have demonstrated a low incidence of side effects and a significant decrease in intubation rates and in-hospital mortality.[33] The meta-analysis of NIV trials reveals significant reductions in mortality (95% CI RR=0.35–0.76) and the need for intubation (95% CI RR=0.33–0.53) – the number of patients needed to avoid one intubation or death being as few as 4 and 10 respectively.[34] Risk reduction appears to be proportional to the severity of respiratory acidosis.[35] The incidence of nosocomial pneumonia is lower with NIV[36–38] and this may explain some of the survival benefit associated with NIV.[38]

Current evidence supports the use of NIV in hypercapnic ARF as a component of standard therapy in COPD subjects. This is supported by many respiratory medicine societies throughout the world[18,30,39] that 'patients hospitalised for exacerbations of COPD with rapid clinical deterioration should be considered for noninvasive positive pressure [ventilatory support] to prevent further deterioration in gas exchange, respiratory workload and the need for endotracheal intubation'.[18]

All modes of NIV have been shown to be effective but there are no comparative trials that address the question of optimal mode or pressure level.[18] Patients with ARF arising predominantly from reversible airflow obstruction (P_{res}) and/or threshold load are likely to respond to CPAP alone. Hypercapnic patients often have reduced alveolar ventilation or respiratory muscle insufficiency and are therefore likely to benefit from the addition of inspiratory support, such as PSV, IPAP, or NIPPV.

A trial of NIV is justified by the presence of respiratory acidosis (pH<7.37) or persistent breathlessness.[34,40] It is poorly tolerated in those without acidosis.

Inspiratory support (usually 5–20 cmH_2O) should be titrated to improve V_E as indicated by improvement in tidal volume and pH, and reduction in respiratory rate and/or Pa_{CO_2}. Low levels of CPAP or EPAP (4–8 cmH_2O) are usually required to counterbalance threshold load. Clinical observation and judgement are required to titrate this to a level that minimises the effort required to trigger inspiratory support (PSV or IPAP). Fi_{O_2} is titrated to reverse hypoxia.

Early predictors of NIV success in COPD patients include improvements in pH and Pa_{CO_2} (but not Pa_{O_2}) within the first 1–2 hours of therapy.[34,40] Predictors of NIV failure include persistent mask intolerance, severe acidosis (pH<7.25), tachypnoea (>35/min), impaired conscious state, and poor clinical response to initial therapy.[41] The bedside care plan should include a clear strategy for those patients who fail a trial of NIV. Mask intolerance, nursing workload, and failure rates are greater during NIV for COPD than those reported in CPO. These patients benefit from a critical care setting where expertise and equipment are available and reported outcomes appear better.[19,34]

Whilst reported success rates are high (70–90%), NIV failure (i.e. intubation) appears to increase with the severity of respiratory acidosis.[34,40] For the poorly compliant patient, reassurance and explanation together with a trial of different size and/or type of mask, or initiation with lower-pressure settings, and brief periods of NIV will sometimes assist. Low-dose anxiolytic drugs may be beneficial where anxiety is a recurrent precipitant of dyspnoea, but should be used with extreme caution because of their respiratory depressant side-effects.

Late failure (>48 h) occurs in 10–20% of patients[20,32,41] despite an initial improvement with NIV. This group of patients has a high mortality risk.[42] Whether this reflects the severity of the underlying disease or delayed initiation of MV remains unclear.

ASTHMA

Asthma is an acute inflammatory lung disease that increases resistive (P_{res}) and threshold ($PEEP_i$) respiratory work. Physiological and clinical improvement has been demonstrated in acute asthmatics with the application of CPAP[43–45] and bilevel NIV.[45–47] One randomised controlled trial of bilevel NIV titrated over 30 minutes resulted in significant improvement in $FEV_{1.0}$ and a lower hospital admission rate.[48]

The clinical role of NIV in the management of acute asthma and the benefit of differential inspiratory and expiratory pressures remains to be clarified. Nebulised drugs can be effectively delivered even in the presence of a high-flow NIV circuit.[49] Controlled clinical studies with robust end-points are awaited. We have found 5 cmH_2O CPAP to be effective in moderate to severe asthma not responding to steroids and continuous inhaled bronchodilators, and that mask intolerance is the most common cause for failure. If NIV is used in asthma this must be performed in a high-acuity environment where there appropriately skilled staff members are immediately available should the patient require urgent intubation.

ACUTE LUNG INJURY (ALI) AND ACUTE RESPIRATORY DISTRESS SYNDROME (ARDS)

Like CPO, ALI leads to an increase in elastic workload (P_{el}) and, to a lesser extent, resistive workload (P_{res}) arising from an increase in alveolar–capillary permeability, the release of inflammatory mediators, and impaired surfactant function. Even though the addition of PEEP is beneficial (during MV) for ALI or ARDS and NIV has a lower prevalence of nosocomial pneumonia,[36–38] current data do not support the routine use of NIV in non-cardiogenic pulmonary oedema and undifferentiated hypoxaemic acute respiratory failure.[50,51]

Despite numerous publications reporting the successful use of NIV in the setting of community-acquired pneumonia (without COPD) and other forms of ALI, the failure rate remains high.[33,50–55] This may reflect the differences in duration, severity, and the pathophysiology of pneumonia, ALI and ARDS compared with CPO. Apparent benefit may be due to the inclusion of subjects with cardiogenic pulmonary oedema[56] or COPD[57,58] – specific subgroups known to benefit from NIV.

PNEUMONIA IN THE IMMUNOCOMPROMISED PATIENT

MV is associated with high morbidity and mortality risks in immunocompromised patients with hypoxic respiratory failure.[58–61] These patients may benefit from an early trial NIV since this appears to be associated with improved hospital survival.[61] Whether NIV simply avoids a high-morbidity therapy (MV)[36] or identifies responders with a more readily reversible form of ARF is unclear. Nevertheless it seems reasonable, based on the current data, to offer NIV to these patients.[18,61] Once again, clear bedside guidelines should be established for the management of patients who fail a trial of NIV and those in whom MV is deemed inappropriate or futile because of its high associated mortality risk.[61]

POSTOPERATIVE AND POST-TRAUMATIC ARF

ARF in postoperative and trauma patients may arise from a number of reversible pathological processes associated with increases in elastic workload (P_{el}) and impaired respiratory muscle function (P_{mus}), including dependent atelectasis, impaired chest-wall mechanics, poor cough, nosocomial infection, aspiration pneumonitis and non-respiratory trauma or sepsis.

Mask CPAP consistently improves intermediate physiological parameters (e.g. oxygenation and respiratory rate) and reduces the risk of intubation in general surgical[62] and cardiothoracic patients[63] with mild postoperative hypoxic respiratory failure, but evidence for a survival benefit is lacking. NIV may improve survival in certain subgroups such as postoperative lung resection[64] but many of these patients have underlying COPD, and extrapolation of these results to non-COPD patients awaits further study.

Mask CPAP has been shown to be superior to MV in patients with isolated severe chest trauma,[65,66] but the benefit of NIV remains unclear. NIV is contraindicated in the presence of other significant injuries such as neurotrauma and intracranial hypertension, facial trauma or the presence of an untreated pneumothorax.

NIV-ASSISTED WEANING

Since NIV is effective in reducing the need for intubation and MV, it has been postulated that NIV may prevent re-intubation. NIV has therefore been recommended to expedite early weaning from MV[67] or as rescue therapy following failed[68] or accidental extubation. The putative advantages relate to reduction in the duration and the risks of MV (e.g. nosocomial pneumonia).

For COPD patients there appears to be a survival benefit[67–69] but it cannot be recommended in the non-COPD group, for whom NIV offers no benefit[18,70,71] or even increased mortality.[68] Although NIV is an option for post-extubation rescue therapy in the COPD subgroup, it is not a substitute for strategies to improve early access to NIV (in COPD and CPO) and improve weaning success and the risk of premature extubation.

NIV AND CHRONIC RESPIRATORY DISEASE

NIV is an important modality for short-term assistance and long-term treatment of severe chronic respiratory failure associated with obstructive and central sleep apnoea syndromes,[18,72] and chronic hypoventilation syndromes associated with extrapulmonary disease such as neuromuscular disease,[72] and thoracic deformities.[73,74] There appears to be less benefit in chronic parenchymal lung disease such as (stable) COPD[69,74–6] and cystic fibrosis (CF).[77]

These patients may require short-term respiratory support during an acute illness or as an aid to perioperative care in a critical care environment. NIV (plus mini-tracheostomy for secretion removal) may improve outcome compared with intubation and MV[73] but failure rates appear to be higher than in hypercapnic COPD.[76] Diagnosis of these underlying disorders during admission for treatment of severe ARF should prompt referral and assessment for long-term NIV.

NIV AND SLEEP APNOEA SYNDROMES[78,79]

Moderate or severe OSA results in nocturnal hypoventilation and episodic hypoxia that can lead to pulmonary and systemic hypertension, cardiac failure, and daytime hypercapnia and somnolence.[80,81] Many of these complications can be arrested or reversed through the appropriate use of nocturnal CPAP.[18,74,77] Patients with suspected sleep apnoea require accurate assessment by a respiratory physician, including sleep studies, prior to the routine use of domiciliary CPAP. Bilevel or controlled ventilation is required when there is inadequate central respiratory drive or increased elastic work. In many patients respiratory drive will improve, and they can then be managed with CPAP after a period of bilevel or controlled ventilation.

Intercurrent illness, surgery, or the use of sedatives and opioid analgesics, will increase the frequency and duration of hypopnoea, apnoea and hypoxia. CPAP should be available even for those patients who do not require admission to a critical care ward.

NIV AND CHRONIC HYPOVENTILATION SYNDROMES

Domiciliary NIV (predominantly using inspiratory support modes or NIPPV) should be considered in all patients presenting with severe chronic respiratory failure due to neuromuscular disease.[72,74,82] Early referral and consideration of domiciliary NIV are recommended because of improved outcomes[72,83,84] and quality of life. In CF patients it may have a role simply as a bridge to organ transplantation.[59,77] In direct contrast to the role of NIV in acute exacerbations of COPD, there is little or no benefit of domiciliary NIV in the presence of stable COPD[18,39,75,76] unless one of the former conditions coexists.

Assessment of these patients for domiciliary NIV includes respiratory function tests, blood gas analysis and sleep studies, together with trials of NIV modes and pressure settings. In general, indications for long-term NIV include the demonstration of symptomatic respiratory failure, daytime hypercapnia and a significantly reduced (<20% predicted) vital capacity. The use of nocturnal or intermittent NIV has been shown to improve daytime respiratory and cardiac function, to improve exercise endurance, to slow the progression of respiratory dysfunction, and to reduce the frequency of hospitalisation.[72,85]

Respiratory monitoring

Andrew D Bersten

History and respiratory examination are particularly important in the critically ill patient. Particular attention should be directed at the respiratory rate (f), the most poorly documented vital sign, the quantity and nature of sputum, and evidence of excessive inspiratory and/or expiratory pleural pressure changes and effort, which include accessory muscle use, tracheal tug, supraclavicular and intercostal indrawing, paradoxical abdominal movement (which is suggestive of diaphragmatic fatigue[1]), and pulsus paradoxus. During spontaneous ventilation an excessive fall in blood pressure during inspiration (>10 mmHg) is found both in low-output states such as cardiac tamponade, cardiogenic shock, pulmonary embolism, hypovolaemic shock, and in acute respiratory failure. The fall in pleural pressure during spontaneous inspiration has a curvilinear relationship with the fall in blood pressure. However, as there is marked variation between individuals,[2] pulsus paradoxus is most useful in following trends. A reduction in the degree of paradox may reflect improvement with a fall in the negative pleural pressure needed for ventilation, or may reflect respiratory muscle insufficiency, and an inability to generate the same negative pleural pressure.

Additional information can be gained from blood gases and pulse oximetry (Ch. 18), and capnography, ventilatory pressures, and waveform analysis in patients receiving respiratory assistance. This chapter will focus on tests of respiratory function that are directly relevant to critically ill patients.

MONITORING GAS EXCHANGE

OXYGENATION

This is reviewed in Chapter 18, and is only briefly discussed here. Hypoxaemia may be due to a low partial pressure of inspired O_2 (rare), hypoventilation, diffusion impairment (rare), ventilation–perfusion ($\dot{V}/\dot{Q}$) mismatch, and shunt. Inert gas analysis has been used to quantitate $\dot{V}/\dot{Q}$ mismatch, and has demonstrated that hypoxaemia in ARDS is predominantly due to alveoli that are perfused but not ventilated (shunt),[3] consistent with CT scan evidence of increased dependent lung density. The alveolar gas equation is a common but less accurate method to assess hypoxaemia:

$$PA_{O_2} = \text{inspired } P_{O_2} - Pa_{CO_2} / \text{respiratory quotient} \quad (38.1)$$

where PA_{O_2} is the alveolar PO_2, and this is usually simplified to:

$$PA_{O_2} = (760 - 47) \times Fi_{O_2} - Pa_{CO_2} / 0.8 \quad (38.2)$$

where 760 is atmospheric pressure in mmHg, and 47 is the saturated vapour pressure of water at 37°C, since gas at the alveolus is fully humidified. The normal PA_{O_2} to Pa_{O_2} gradient is less than 15 mmHg, but increases to 25 mmHg in the elderly. This normal A–a gradient is due to some venous admixture through the lungs, and a small right-to-left shunt through both the bronchial veins, and the thebesian veins of the coronary circulation. This equation removes hypercarbia as a direct cause of hypoxaemia, and an increase in the A–a gradient will usually be due to $\dot{V}/\dot{Q}$ mismatch or right-to-left shunt. A commonly used alternative measure of hypoxaemia is the Pa_{O_2}/Fi_{O_2} ratio. However, this does not account for the effect of a raised Pa_{CO_2}, and both measures are influenced by a number of factors (e.g. cardiac output, Hb, Fi_{O_2}) in addition to the extent of venous admixture, which may be estimated from the intrapulmonary shunt equation:

$$\dot{Q}_s / \dot{Q}_t = Cc'_{O_2} - Ca_{O_2} / Cc'_{O_2} - Cv_{O_2} \quad (38.3)$$

where $\dot{Q}_s$ is the intrapulmonary shunt blood flow, $\dot{Q}_t$ is the total pulmonary blood flow, Cc'_{O_2} is the end-capillary O_2 content calculated from the PA_{O_2}, and Ca_{O_2} and Cv_{O_2} are the O_2 contents of arterial and mixed venous blood respectively.

CARBON DIOXIDE

Pa_{CO_2} is determined by alveolar ventilation ($\dot{V}_A$), and CO_2 production ($\dot{V}_{CO_2}$):

$$Pa_{CO_2}(\text{mmHg}) = \dot{V}_{CO_2}(\text{mL / min STPD}) \times 0.863 / \dot{V}_A(\text{L / min BTPS}) \quad (38.4)$$

where $\dot{V}_A$ is the minute ventilation ($\dot{V}_E$) minus the wasted or dead space ventilation ($\dot{V}_D$). The modified Bohr equation (assuming $PA_{CO_2}=Pa_{CO_2}$) calculates the proportion of the V_T that is wasted ventilation (i.e. physiological dead space; V_{Dphys}):

$$V_{Dphys} / V_T = Pa_{CO_2} - P\bar{E}CO_2 / Pa_{CO_2} \quad (38.5)$$

where $P\bar{E}_{CO_2}$ is the mixed expired P_{CO_2}, and V_{Dphys} is composed of anatomical dead space (V_{Danat}) and alveolar dead space (V_{Dalv}) – notionally due to alveoli that are ventilated but not perfused. Normally V_{Dalv} is minimal and V_{Danat} comprises 30% of V_T. Since the volume of an endotracheal tube is less than the mouth or nose, and pharynx, intubation may reduce V_{Danat}; however, when the connection from the endotracheal tube is taken into account there is little change in dead space. Positive pressure ventilation increases dead space by distension of the airways increasing V_{Danat}, and through a tendency to increase alveoli that are ventilated but not perfused. In patients with ARDS, marked increases in V_{Dalv} lead to marked increases in the V_{Dphys}/V_T ratio (exceeding 0.6), which is an independent prognostic factor.[4]

CAPNOGRAPHY

Capnography measures and displays exhaled CO_2 throughout the respiratory cycle, with sampling usually by a mainstream sensor as sidestream systems tend to become blocked by secretions. However, when capnography is used in non-intubated patients, sidestream sampling is commonly used (*e.g.* modified nasal cannulae). Infrared spectroscopy measures the fraction of energy absorbed and converts this to a percentage of CO_2 exhaled. During expiration the capnogram initially reads no CO_2, but as anatomical dead space is exhaled there is a rise in the exhaled CO_2 to a plateau, which falls to 0% CO_2 with the onset of inspiration. In patients with significant respiratory disease a plateau may never be achieved. The end-tidal CO_2 (PE'_{CO_2}) is the value at the end of the plateau, and is normally only slightly less than the Pa_{CO_2}. However, this gradient will increase when alveolar dead space (V_{Dalv}) increases, such as low cardiac output, pulmonary embolism and elevated alveolar pressure. Consequently the PE'_{CO_2} may not reflect Pa_{CO_2} in critically ill patients. Nevertheless, in a stable patient the gradient will be fairly constant, and can be used to guide $\dot{V}_E$ during transport,[5] and when other factors including the adequacy of minute ventilation are unchanged then sudden changes in the PE'_{CO_2} may provide an early signal. Indeed, PE'_{CO_2} directly correlates with cardiac output, and PE'_{CO_2} monitoring has been used to assess adequacy of cardiopulmonary resuscitation, and its prognosis.[6]

The presence of exhaled CO_2 confirms endotracheal tube placement, and is recommended even when the tube is seen to pass through the vocal cords,[7] since clinical assessment is not always reliable. Simple colorimetric devices may be used for this purpose. However, detection of expired CO_2 is not infallible[7] as false positives can rarely occur following ingestion of carbonated liquids, and false negatives may be due to extremely low pulmonary blood flow, or very large alveolar dead space such as pulmonary embolus or severe asthma. Monitoring with capnography is also recommended for transport[8] and respiratory monitoring[9] in critically ill patients, and should be available for every anaesthetised patient.[10]

GAS TRANSFER (DIFFUSING CAPACITY)

This is a test of the transfer of a gas, typically carbon monoxide (CO), across the alveolocapillary barrier. The transfer factor is calculated as:

$$\text{volume of CO taken up} / (PA_{CO} - Pc_{CO}) \qquad (38.6)$$

and, as CO is so completely taken up by Hb, Pc_{CO} is taken as zero. This test is usually performed as an outpatient, is not usually measured in ICU, and diffusion abnormality is rarely a cause of hypoxaemia. The transfer factor is often corrected for lung volume since diseases such as emphysema and pulmonary fibrosis may affect both lung volume and diffusion. In chronic heart failure diffusing capacity is reduced and correlates with exercise performance and CHF severity and prognosis, due to a reduction in the volume of alveolar tissue and amount of blood participating in gas exchange.[11]

LUNG VOLUME AND CAPACITIES (Fig. 38.1)

The tidal volume (V_T) is the volume of gas inspired and expired with each breath, and the volume at end expiration is the functional residual capacity (FRC). The residual volume (RV) is the FRC minus the expiratory

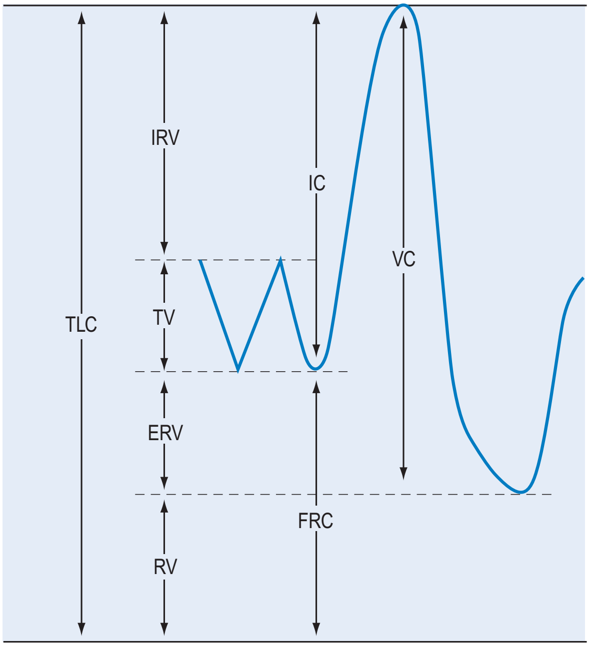

Figure 38.1 Lung volumes and capacities. TLC=total lung capacity; IRV=inspiratory reserve volume; TV=tidal volume; ERV=expiratory reserve volume; RV=residual volume; IC=inspiratory capacity; FRC=functional residual capacity; VC=vital capacity.

reserve volume (ERV). If a maximum inspiratory effort is made from FRC this is termed a vital capacity (VC) manoeuvre when the total lung capacity (TLC) is reached. Clinically, the most important of these are the FRC, V_T, and VC, and the latter two are easily measured using a spirometer or integrated from flow.

TIDAL VOLUME

Minute volume is composed of f and V_T; normally ~17 breaths/min and ~400 mL respectively in adults.[12] Rapid shallow breathing is common in patients with respiratory distress, and in those failing weaning. Although the f/V_T ratio>100 was initially shown to be highly predictive of weaning failure,[13] subsequent studies have reported varying results.

VITAL CAPACITY

At TLC inspiratory muscle forces are counterbalanced by elastic recoil of the lung and chest wall. Both these parameters and the size of the lung, which varies with body size and gender (**Box 38.1**), determine TLC. Vital capacity, the difference between TLC and FRC, is also reduced by factors that reduce FRC, *e.g.* increased abdominal chest wall elastance and premature airway closure in COPD. The normal VC is ~70 mL/kg; although reduction to 12–15 mL/kg has been suggested as an indication for mechanical ventilation, many other factors need to be considered including the patient's general condition, the strength of the expiratory muscles, glottic function, and the response to non-invasive ventilation. Indeed, many chronically weak patients are able to manage at home with extremely low VC with the assistance of non-invasive ventilation.

Box 38.1 Factors that decrease vital capacity

Decreased muscle strength
- Myopathy
- Neuropathy
- Spinal cord injury

Increased lung elastance
- Pulmonary oedema
- Atelectasis
- Pulmonary fibrosis
- Loss of lung tissue

Increased chest wall elastance
- Pleural effusion
- Haemothorax
- Pneumothorax
- Kyphoscoliosis
- Obesity
- Ascites

Reduced functional residual capacity
- Atelectasis
- Premature airway closure (e.g. chronic obstructive pulmonary disease)

FUNCTIONAL RESIDUAL CAPACITY

Direct measurement of FRC is rare in ICU. Anatomical rather than functional estimates can be derived from CT scan: however, techniques such as nitrogen or oxygen washout[14] are becoming available on modern ventilators. When FRC is less than the closing volume, the lung volume at which airway closure is present during expiration, there is a marked increase in $\dot{V}/\dot{Q}$ mismatch. Consequently, PEEP is commonly used to elevate FRC. Increases in lung volume above resting lung volume can be directly measured from a prolonged expiration to atmospheric pressure using either a spirometer or integration of flow,[15] or by repeated FRC measurements. FRC is decreased in ARDS and pulmonary oedema, in patients with abdominal distension, and following abdominal and thoracic surgery. Increased FRC places the diaphragm at a mechanical disadvantage, and is seen with severe air-flow limitation and dynamic overinflation, and when there is loss of elastic recoil (e.g. emphysema).

ELECTRICAL IMPEDANCE TOMOGRAPHY (EIT)

EIT uses impedance variation (as gas is a poor conductor) derived from multiple chest wall electrodes to monitor regional tidal ventilation. This is usually performed following a recruitment manoeuvre or change in PEEP setting.[16] Care must be taken to differentiate the diaphragm from collapsed lung, as the diaphragm moves cephalad both during expiration and at lower lung volumes. EIT can be calibrated to volume, and used to examine changes in end-expiratory lung volume but not FRC itself. PEEP may be adjusted to these changes and to indices of heterogeneity of ventilation; however, this does not define the balance between recruitment and overdistension. Currently EIT is a promising research tool, which may have application for tailoring ventilation.

MEASUREMENT OF LUNG MECHANICS

The forces the respiratory muscles must overcome during breathing are the elastic recoil of the lung and chest wall, and airway and tissue resistance. During controlled mechanical ventilation the ventilatory pressures reflect the work done to overcome these forces; however, during partial ventilatory support the pressure at the airway opening reflects both these forces and those generated by the respiratory muscles. Estimates of respiratory mechanics are often readily available, and can assist titration of ventilatory support.

ELASTIC PROPERTIES OF LUNG AND CHEST WALL

The respiratory system (RS) is composed of the lung (L), and chest wall (CW), which is comprised of the rib cage and abdomen. Although it is often convenient to

consider respiratory system mechanics as implying information about the lung, abnormal chest wall compliance can markedly influence these measurements.[17–20]

The pressure gradient across the lung (P_L) that generates gas flow is equal to the difference between the pressure at the airway opening (P_{ao}) and the mean pleural pressure (P_{pl}), which is estimated as the oesophageal pressure (P_{es}):

$$P_L = P_{ao} - P_{es} \tag{38.7}$$

Although the P_{es} is not always an accurate measure of the absolute P_{pl}, the change in P_{es} reflects the change in P_{pl}. However, this requires an appropriately positioned and functioning oesophageal balloon. In spontaneously breathing subjects a thin latex balloon sealed over a catheter is introduced into the lower third of the oesophagus and P_{es} and P_{ao} measured simultaneously during an end-expiratory airway occlusion. A well-positioned oesophageal balloon will have a ratio of $\Delta P_{es}/\Delta P_{ao}$ of ~1.[21] This technique is reliable in supine, intubated spontaneously breathing patients[22] and in paralysed subjects it appears that a similar pressure change, induced by manual rib cage pressure,[23] can be used to verify oesophageal balloon function.

Chest wall mechanics are derived from P_{es} referenced to atmospheric pressure and, in ventilated relaxed subjects, respiratory system mechanics are derived from P_{ao} referenced to atmospheric pressure. It is not surprising then that $P_{RS}=P_L+P_{CW}$. Finally, abdominal mechanics can be estimated as either intravesical or intragastric pressure. However, despite these provisos, useful information can be obtained from respiratory system mechanics.

Measuring the slope of the V–P relationship of the lung or respiratory system allows a simple estimate of the elastic properties of the lung. Since the E_{RS} is directly related to its components ($E_{RS}=E_L+E_{CW}$), it is preferred to compliance, which is inversely related: $1/C_{RS}=1/C_L+1/C_{CW}$. The normal E_{RS} is 10–15 cmH_2O/L and the normal C_{RS} is 60–100 mL/cmH_2O in ventilated patients.

MEASUREMENT OF ELASTANCE

Elastance and resistance are frequency dependent, and respiratory mechanics depend upon the volume and volume history of the lung.[24] With increasing frequency of breathing, total respiratory system resistance falls and elastance increases, and this is particularly obvious in patients with air-flow obstruction.[25,26] Consequently these factors must be taken into account when interpreting respiratory mechanics. In a passively ventilated subject P_{ao} is the sum of: (i) the pressure required to overcome airway, endotracheal tube and circuit resistance (P_{res}), (ii) the elastic pressure required to expand the lung and chest wall (P_{el}), (iii) the elastic recoil pressure at end expiration or total PEEP (P_o), and (iv) the inertial pressure required to generate gas flow (P_{inert}):

$$P_{ao} = P_{el} + P_{res} + P_o + P_{inert} \tag{38.8}$$

Since the elastance (E), is equal to $\Delta P/\Delta V$, with the resistance (R) equal to $\Delta P/\Delta\dot{V}$, and ignoring the inertance,[27] this can be rewritten as the single-compartment equation of motion:

$$P_{ao} = E_{RS}V + R_{RS}\Delta\dot{V} + P_o \tag{38.9}$$

Elastance can then be measured using either static techniques, where cessation of gas flow allows dissipation of P_{res}, or dynamic techniques, where flow is not interrupted.

END-INSPIRATORY OCCLUSION METHOD

The simplest estimate of E_{RS} can be made using a rapid end-inspiratory airway occlusion during a constant flow breath, provided that the respiratory muscles are relaxed (**Fig 38.2**). If a plateau is introduced at end inspiration there is a sudden initial pressure drop due to dissipation of flow resistance ($P_{pk}-P_1$) followed by a slower, secondary pressure drop to a plateau

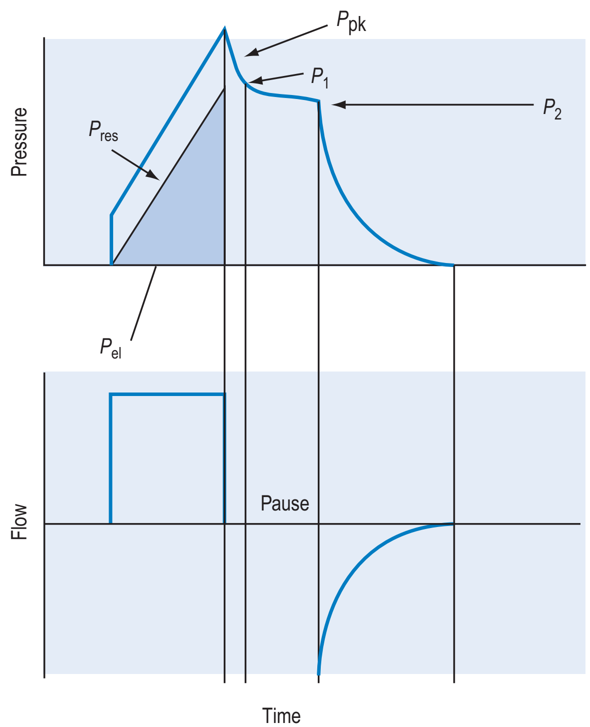

Figure 38.2 Schematic diagram of a volume-controlled breath with constant inspiratory flow. A period of no inspiratory gas flow has been interposed before expiration (pause) to illustrate dissipation of lung resistance as airways resistance (fall from P_{pk} to P_1) and tissue resistance (fall from P_1 to P_2). The inspiratory pressure due to the elastic properties of the respiratory system is illustrated as the filled area (P_{el}), and the lung resistive pressure is labeled as P_{res}. (See text for more detail.)

($P_{dif}=P_1-P_2$) due to stress relaxation. At least 1–2 seconds are taken for this plateau to be achieved, and P_2 is often called the plateau pressure; however, if P_{plat} is measured too soon it will lie somewhere between P_1 and P_2.

Stress adaptation

Stress relaxation of the respiratory system is due to both tissue viscoelasticity and time constant inequalities of the respiratory system (pendelluft). In the normal lung pendelluft has a minimal contribution to stress relaxation.[28] However, heterogeneity of regional resistance and elastance can markedly influence stress relaxation.[29] Pulmonary surfactant and its contribution to changes in surface tension, parenchymal factors including elastic fibres in the lung, contractile elements such as the alveolar duct muscle and changes in pulmonary blood volume have all been implicated in the viscoelastic properties of the lung. In the abnormal lung it is difficult to separate either of these factors or the role of pendelluft in stress adaptation.

Calculation of respiratory mechanics

Returning to Figure 38.2, it is now simple to estimate respiratory system resistance and elastance from P_{ao}. The static elastance ($E_{rs,st}$) and the dynamic elastance ($E_{rs,dyn}$) are calculated as:

$$E_{rs,st} = (P_2 - P_o) / V_T \quad (38.10)$$

$$E_{rs,dyn} = (P_1 - P_o) / V_T \quad (38.11)$$

where P_o is the total PEEP (extrinsic plus intrinsic PEEP). The difference between $P_{el,dyn}$ and $P_{el,st}$ is the effective recoil pressure of the respiratory system during mechanical ventilation. Consequently, additional work is performed during inspiration to overcome stress adaptation, and this is stored and dissipated during expiration. This contributes to the hysteresis seen in dynamic volume–pressure curves during mechanical ventilation, and to the generation of expiratory flow. This latter component may be important in patients with air-flow obstruction since the imposition of a pause at end inspiration results in a 32% dissipation of the total energy loss within the respiratory system.[30]

THE STATIC VOLUME–PRESSURE CURVE

The quasistatic volume–pressure (V–P) curve is infrequently performed, and the relevance of a measurement performed on a single occasion is questionable when lung mechanics are not constant. Various techniques have been described, but the overall concept is that incremental volume and pressure points are made after a sufficient period of no flow has allowed P_{res} to be dissipated. This allows definition of a sigmoidal-shaped curve with upper and lower inflection points, and a mid-section with relatively linear V–P relations, allowing inflation elastance to be measured as this slope at a given lung volume. If similar measures are made during deflation a deflation curve and its hysteresis can also be described.

The V–P curve provides an advantage over an end-inspiratory elastance as, with the latter, it is not possible to know which part of the V–P curve is being measured. Consequently this ‘chord’ elastance may span either inflection point, yielding a falsely high figure. The upper inflection point represents a sudden decrease in elastance with increasing volume, and this has been interpreted as lung overinflation. The lower inflection point represents a sudden decrease in elastance with increased volume, and this has been interpreted as recruitment of atelectatic air spaces. Ventilation between these two inflection points should minimise both shearing forces secondary to repetitive collapse and reopening of alveoli, and overstretch of alveoli. However, this interpretation of the V–P curve has been questioned. In patients with ARDS, recruitment occurs well above the lower inflection point, along the entire V–P curve and above the upper inflection point.[31, 32] An alternative interpretation is that the lower inflection point represents a zone of rapid recruitment, and that the upper inflection point is due to a reduced rate of recruitment.[33]

Conventionally the static V–P curve has been measured in paralysed ventilated patients with the ‘super-syringe’ method.[34] In a paralysed patient the respiratory system is progressively inflated from FRC in 100 mL steps up to ~1700 mL or a predefined pressure limit. After each step sufficient time is allowed for a well-defined plateau to become apparent (using a pause of 3–6 seconds). The effects of temperature, humidity, gas compression and ongoing gas exchange during the manoeuvre need to be taken into account,[35,36] and the volume history standardised before it is performed. Many patients become hypoxaemic following disconnection from the ventilator during the 60 seconds or so without PEEP. An alternative is to randomly insert a range of single-volume inflations, followed by a prolonged pause,[37] during normal mechanical ventilation at 0 cmH_2O PEEP. Advantages include simplicity, the patient is not disconnected from the ventilator, the volume history is the same for each measurement and gas exchange during the measurement is negligible. However, again, many patients will become hypoxaemic due to prolonged periods without PEEP (this procedure may take ~15 minutes), particularly following a small-volume breath. Finally, an automated low-flow V–P curve method allowing subtraction of P_{res} is available on some ventilators, takes around 20 seconds to perform, and correlates well with the static occlusion technique.[38,39]

THE DYNAMIC V–P CURVE

Dynamic P_{ao}, $\dot{V}$ and V are displayed by many ventilators, but the volume signal is not referenced to FRC and the signals are not readily available for quantitative analysis. However, $\dot{V}$ is readily measured with a heated

pneumotachograph, and volume can then be derived by simple integration. If P_{ao} is also collected it is relatively simple to measure dynamic mechanics.

The dynamic V–P curve appears to show hysteresis, due to the effects of airway and tissue resistance; however, during tidal breathing even the static V–P does not show hysteresis.[40] In contrast to static V–P relations, dynamic mechanics are collected during normal ventilation so they do not interfere with patient care, and they provide a 'functional' description of respiratory mechanics. Indeed the 'effective' alveolar distending pressure is more accurately $P_{el,dyn}$, not $P_{el,st}$. Since dynamic mechanics are potentially continuous they could also be used to servo-control ventilatory strategies.

There are a number of ways to analyse dynamic V–P data. A line can be drawn between no-flow points at end inspiration and end expiration to determine elastance; however, this is relatively inaccurate as it is based on two points that can be hard to exactly identify. Multiple linear regression analysis is now the technique most commonly employed. The patient does not need to be paralysed[41] provided the respiratory muscles are not active during ventilation. The signal can also be split to allow analysis of inspiratory and expiratory mechanics.

Provided the model fit is acceptable, elastance and resistance are accurately and reproducibly calculated using the single compartment equation of motion:

$$P_{ao} = E_{RS}V + R_{RS}\Delta\dot{V} + P_o \qquad (38.12)$$

Static $PEEP_i$ is accurately calculated, as $P_o - PEEP_e$, when compared with either an end-expiratory airway occlusion method[42] or by direct measurement of end-expiratory alveolar pressure.[43] However, the single compartment model only approximates the respiratory system, and frequency and volume dependence of the derived mechanics are observed.

Changes in elastance during tidal breathing can be modeled with the stress index derived from power analysis of the P_{ao}–t curve ($P_{ao} = a^t + c$),[44] and addition of a volume-dependent term to the equation of motion:[14,45]

$$P_{ao} = (E_1 + E_2V)V + R_{RS}\Delta\dot{V} + P_o \qquad (38.13)$$

$$E_{rs} = E_1 + E_2V \qquad (38.14)$$

Since power analysis requires a constant inspiratory $\dot{V}$ pattern to discount resistive effects, it is not as versatile as the volume-dependent technique, which models resistance and can be applied to any inspiratory $\dot{V}$ pattern. Both measures correlate highly with each other suggesting they measure the same parameter.

High stress, and possibly overinflation, is inferred when the stress index is greater than 1.1 and when the volume-dependent elastance increases, which may be quantified:

$$\%E_2 = 100E_2V / E_{rs} \qquad (38.15)$$

A stress index below 0.9 and a negative volume dependence (negative $\%E_2$) suggest significant atelectasis during tidal breathing. Provided both V_T and $\dot{V}$ are constant, the change in driving pressure, either $P_{pk} - PEEP_{tot}$ or $P_1 - PEEP_{tot}$ 20–30 minutes following a change in PEEP is highly correlated with $\%E_2$.[14] Using the 95% predictive interval for these data, an increase in $\Delta P > 2$ cmH_2O, consistent with a significant increase in elastance, suggests high stress and overinflation. Similarly, the lowest E_{rs} during PEEP titration targets the best balance between recruitment and overinflation, and may be superior to the stress index or $\%E_2$ in laboratory models.[46]

Both the stress index and volume-dependent elastance also vary with stress relaxation, and high stress may not mean overinflation; in COPD bullous lung disease is due to a loss of lung tissue and elastic recoil. This may be measured on CT as hyperaerated; however, the associated wall stress may be high or low depending upon the degree of inflation.

INTERPRETATION OF ELASTANCE

Elastance may be increased due to a reduction in lung volume or to an increase in specific elastance, the product of E and FRC. Small body size, female gender, lung resection and reduced aerated lung volume (e.g. ARDS) are important factors in reducing effective lung volume. Specific elastance is increased in ARDS, pulmonary oedema and pulmonary fibrosis.

MEASUREMENT OF THE RESISTANCE OF THE LUNG AND CHEST WALL

Lung resistance (R_L) is the sum of airway (R_{aw}) and tissue resistance (R_{ti}). Resistance is flow-, volume- and frequency-dependent, and R_L decreases as f increases. It is also important to compare measurements at similar lung volumes since there is a hyperbolic relation between lung volume and R. This is particularly obvious in ARDS where the incremental administration of PEEP can result in a decrease in R_{aw} due to concurrent recruitment and an increase in lung volume. Indeed, although the absolute values are increased, when corrected for end-expiratory lung volume R_L, R_{aw} and R_{ti} are unchanged in ARDS,[15] although specific R_{ti} did increase with PEEP.[17] Finally, since gas flow may be a mixture of laminar and turbulent flow, resistance is often flow-dependent.

END-INSPIRATORY OCCLUSION TECHNIQUE

The total inspiratory R_{aw}, including the endotracheal tube and associated ventilatory apparatus, can be calculated in a relaxed patient following an inspiratory pause (see Fig. 38.2) as:

$$R_{aw} = (P_{pk} - P_1) / \dot{V} \qquad (38.16)$$

and R_L calculated by using P_2 instead of P_1. Since the endotracheal tube and apparatus will make a

significant contribution to R_{aw} it is best to measure P_{ao} distal to the endotracheal tube with an intratracheal catheter. An alternative approach is to calculate and subtract endotracheal tube resistance using the Rohrer equation ($R = K_1 + K_2\dot{V}$),[47] and this is now automatically included in some ventilators. However, as in vivo endotracheal tube resistance is often greater than in vitro resistance,[48] due to the effect of secretions and interaction with the tracheal wall, these corrections may be inaccurate. Despite these provisos, this simple measure of resistance, or the P_{pk} to P_{plat} difference at a constant $\dot{V}$, can be clinically useful in both the diagnosis and monitoring of air-flow obstruction.[49]

DYNAMIC TECHNIQUES

Total, inspiratory and expiratory R can also be estimated, using either multiple linear regression analysis or from linear interpolation of the V–P curve at a constant volume. However, this latter technique assumes a constant elastance during tidal inflation, and may be inaccurate because it relies on only two measurements. Finally, an average expiratory R can be calculated from the time constant (τ) derived from passive expiration if the E is known, since:

$$\tau = R / E \tag{38.17}$$

However, the lung does not empty as a single compartment in patients with air-flow obstruction, and E is assumed to be constant over the tidal expiration.

OTHER MEASUREMENT TECHNIQUES

The interrupter technique consists of a series of short (100–200 ms) interruptions to relaxed expiration by a pneumatic valve.[50] This results in an expiratory plateau in P_{ao} following equilibration with alveolar pressure. From the V, P and $\dot{V}$ data the expiratory elastance and the expiratory P–$\dot{V}$ relationship are measured. This technique does not make assumptions about the behaviour of the respiratory system and can identify dynamic air-flow limitation.

Assuming that the respiratory system behaves linearly, it can be analysed following a forced-flow oscillation at the airway opening.[51] The resultant pressure waveform depends upon the impedance of the respiratory system, which can be analysed following Fourier analysis of the P and $\dot{V}$ waveforms into resistance and reactance. This will then allow measurement of R_{aw}, R_{ti}, E_{rs} and inertance, and information can be gained regarding small airways disease by examining R_{aw} at different oscillatory frequencies.

FORCED EXPIRATORY FLOW

Maximum expiratory flow rates from TLC, the forced vital capacity (FVC), the forced expiratory volume in the first second of expiration (FEV_1) and the peak expiratory flow rate (PEFR) are commonly measured in cooperative subjects with a spirometer or flow meter. The PEFR is cheap but is relatively effort-dependent, and is less specific and reliable than the FEV_1. It is most useful for office or home use. The normal PEFR is 450–700 L/min in males and 300–500 L/min in females. It is reduced with obstructive diseases, and gross muscle weakness.

The FEV_1 is usually expressed as a ratio of the FVC since both may be reduced in restrictive disease, with a normal ratio. The FEV_1 is normally 50–60 mL/kg and 70–83% of FVC. In asthma and COPD the FEV_1 is reduced out of proportion to the FVC to a ratio less than 70%.

MEASUREMENT OF INTRINSIC PEEP

$PEEP_i$ may (a) have unrecognised haemodynamic consequences,[52] (b) adds an elastic load to inspiratory work during assisted and supported ventilatory modes, which may be reduced by application of small amounts of $PEEP_e$,[53] and (c) reflects dynamic hyperinflation with the consequent risks of barotrauma[54] and right heart failure. If $PEEP_i$ is not taken into account during calculation of chord compliance an incorrect denominator is used, which may result in gross error.[55] As automated measures of mechanics do not account for $PEEP_i$, estimates of elastance must be corrected.

The two most commonly described techniques for measuring $PEEP_i$ are end-expiratory airway occlusion in a relaxed subject and the fall in oesophageal pressure during inspiration prior to initiation of inspiratory $\dot{V}$. However, these are not really comparable measures since static and dynamic $PEEP_i$ respectively, are measured. Static $PEEP_i$ is measured as the plateau P_{ao} that is reached following an end-expiratory occlusion; typically a plateau is reached in ~5 seconds, but this will be shorter in ARDS and longer in severe COPD. With the cessation of gas flow, alveolar pressure equilibrates with P_{ao}. Since the lung is composed of non-homogeneous units this will represent the average static $PEEP_i$. All respiratory effort must be absent since muscle pressure will increase end-expiratory P_{ao}. End expiration must be accurately identified. This is most easily done by the ventilator itself either using an end-expiratory hold manoeuvre or by using the next inspiration, the onset of which is concurrent with expiratory valve closure, to close a valve that directs inspiratory flow to atmosphere and seals the circuit. Static $PEEP_i$ is a surrogate measure of dynamic hyperinflation, and this volume may be directly measured using a spirometer[52] or a pneumotachograph[14] during a prolonged expiration.

Dynamic $PEEP_i$ is measured as the pressure change required to initiate inflation. In ventilated subjects this will be the change in P_{ao} prior to initiation of inspiratory $\dot{V}$,[53] and in spontaneously breathing subjects the change in oesophageal[51] or transdiaphragmatic[56] pressure from their end-expiratory relaxation values prior to inspiratory $\dot{V}$. Measurement of dynamic $PEEP_i$ in spontaneously breathing subjects is not particularly

straightforward. The changes in pressure are small and influenced by cardiogenic oscillations, which are preferably filtered out.[57] Furthermore, dynamic PEEP$_i$ is not constant, with breath-to-breath variation probably due to variation in the extent of dynamic hyperinflation. Many patients with air-flow obstruction have an active expiration that 'falsely' increases PEEP$_i$, at least with respect to its elastic load since cessation of active expiration does not require work.[58] Consequently, it is preferable to concurrently measure intragastric pressure as a measure of active expiration.

Finally, PEEP$_i$ can be measured as P_o from dynamic P, V and $\dot{V}$ data in ventilated subjects. This is thought to be a measure of dynamic PEEP$_i$ since static PEEP$_i$ systematically yields a slightly greater result,[42] with similar discrepancies reported between other dynamic measures of PEEP$_i$ and static PEEP$_{i.}$.[59,60] This systematic difference correlates with, and is thought to be due to, the viscoelastic properties and regional time constant inequalities of the respiratory system.[59] This has clinical significance as, although matching dynamic PEEP$_i$ with PEEP$_e$ reduces respiratory work through a decrease in elastic load,[53] it does not counterbalance these forces.

PATIENT–VENTILATOR ASYNCHRONY

Asynchrony between the patient and ventilator is more common than usually recognised during both intubated and non-invasive ventilatory support, and is often due to patient effort failing to trigger the ventilator. Clinical findings include agitation and anxiety, tachycardia, tachypnoea, and increased work of breathing. Careful observation of the patient–ventilator interaction, including waveforms, can be used to further identify and help match ventilatory assistance to neural drive.[61] (See also Ch. 31, Mechanical ventilation.)

INSPIRATION

TRIGGERING OF INSPIRATION

Ineffective respiratory efforts are best detected from the P_{es} waveform; however, this is rarely monitored. Ineffective triggering due to PEEP$_i$ may be detected from the expiratory $\dot{V}$ waveforms as an abrupt decrease in $\dot{V}$ at either the onset of inspiratory muscle activity or relaxation of the expiratory muscles. Monitoring of P_{ao} is less sensitive unless the circuit expiratory resistance is increased (e.g. HME or poorly functioning expiratory valve) so that small changes in expiratory $\dot{V}$ are reflected in P_{ao}. Sensing P_{ao} at the Y-piece does not offer any advantage as the pressure signal needs to travel the same distance via separate gas tubing to the ventilator expiratory block. Inadequate sensitivity may also lead to ineffective triggering with similar but more obvious waveform effects.

Autotriggering, a triggered assisted or supported breath without patient effort, may occur owing to excessively low trigger threshold or to P_{ao} or $\dot{V}$ distortion, as commonly seen with large cardiogenic oscillations, hiccups, condensate in tubing or a circuit leak. Again waveform analysis may help detect and manage the problem; for example, it may be necessary to reduce trigger sensitivity to prevent cardiogenic oscillations from being detected as inspiratory effort.

INSPIRATION

During an assisted volume control breath, P_{ao} may fall, often seen as a scalloped shape, if there is excessive inspiratory muscle effort as seen in $\dot{V}$ starvation. Expiratory muscle effort, as may be seen with an excessive V_T or prolonged inspiratory time (T_i), leads to a rise in P_{ao}. During an assisted pressure control breath or during pressure support, changes in patient effort are detected from the $\dot{V}$ waveform. Finally, excessively rapid development of the set delivered pressure, a rapid rise time, may be detected by an overshoot in P_{ao}; an excessively long rise time will be seen as a rounded inspiratory $\dot{V}$ profile, similar to that seen with continued inspiratory muscle effort.

CESSATION OF INSPIRATION

Mismatch of the mechanical and neural T_i can be detected from waveform changes at the cessation of inspiration.

Mechanical T_i shorter than neural T_i

There will be prolonged inspiratory muscle effort during early expiration; if this leads to a sufficient fall in P_{ao} or $\dot{V}$ an early triggered breath follows. During pressure-cycled ventilation this will lead to a second small I_T breath due to the high baseline lung volume, but in assist volume control P_{ao} will be excessive. Typically this is seen with a stiff respiratory system, PEEP$_i$ or inadequate pressure support.

Mechanical T_i longer than neural T_i

This leads to features of passive inflation such as a linear increase in P_{ao} during assist volume control ventilation; during pressure-cycled ventilation there may be an increase in P_{ao} due to loss of inspiratory effort, or an unexplained fall in $\dot{V}$.

EXPIRATION

Changes in P_{ao} during expiration are usually small unless expiratory circuit resistance is abnormally high. However, in patients with expiratory flow limitation the expiratory $\dot{V}$ waveform shows a typical 'tick' pattern; there is a rapid spike in expiratory flow due to dynamic compression of large conducting airways at the beginning of expiration, and this is followed by low, slowly declining expiratory $\dot{V}$ due to high $\dot{V}$ expiratory resistance. When PEEP$_i$ is present the expiratory $\dot{V}$ fails to cease prior to the inspiratory trigger; however, this may be difficult to detect due to the poor fidelity present on most commercial ventilators.

MONITORING NEUROMUSCULAR FUNCTION

INSPIRATORY OCCLUSION PRESSURE

The pressure 100 ms (P_{100} or $P_{0.1}$) after a random occlusion timed at the beginning of inspiration is a measure of respiratory drive. There is a large range of normal values (1.5–5 cmH_2O), but it is reproducible in an individual patient. In ventilated patients the $P_{0.1}$ correlates with the work of breathing during pressure support ventilation, and changes in the same direction as $PEEP_e$ is increased if work is reduced.[62] Consequently, $P_{0.1}$ may prove to be a useful method of titrating $PEEP_e$ in patients with dynamic hyperinflation; however, this is not valid when flow triggering is used.

MAXIMUM MOUTH PRESSURES

Maximum inspiratory (MIP) and expiratory (MEP) mouth pressures can be used to estimate the power of the respiratory muscles. MIP is usually measured in ventilated patients using a unidirectional expiratory valve for ~20 seconds.[63] This ensures the procedure is performed from a low lung volume and does not require patient cooperation. However, despite this the results are quite variable.[64] Normal values vary with age and gender; young females may exceed ~−90 cmH_2O, and young males ~−130 cmH_2O. A MIP < −20 cmH_2O is predictive of weaning failure; however, this is associated with too many false positives and negatives to be useful.[12] MEP may be useful in myopathic patients with expiratory muscle weakness. Transdiaphragmatic pressure is assessed using an oesophageal and gastric balloon to measure the pressure in these two cavities.

WORK OF BREATHING

The work of breathing (W_B) is the sum of elastic work (W_{el}), flow-resistive work (W_{res}) and inertial work (negligible), and can be estimated from V–P data during spontaneous or assisted ventilation. An oesophageal balloon is used to examine changes in pleural pressure, $\dot{V}$ is measured with a pneumotachograph, and volume is derived as its integral. Although conceptually W_B is the inspiratory area of a V–P loop, this needs to be referenced to the chest wall V–P curve, and the appropriate area measured from a Campbell diagram.[65]

The normal W_B is ~0.5 J/L of $\dot{V}_E$, and this may be significantly increased in patients with acute respiratory failure, and by additional work imposed by ventilatory apparatus including the endotracheal tube and connector, humidifier and ventilator circuit.[66] The consequences of a large increase in W_B may include an increase in the $\dot{V}O_2$ attributable to breathing ($\dot{V}O_{2\,resp}$), respiratory muscle insufficiency, CO_2 retention and acute respiratory failure. However, W_B is rarely measured outside of research projects since the Campbell diagram is a relatively tedious approach. Simplifications have been used, but these are not as accurate, and W_B only estimates energy expenditure during muscle shortening with relatively poor correlation with $\dot{V}O_{2\,resp}$.[67] Consequently, the pressure–time product (PTP), which does correlate with $\dot{V}O_{2\,resp}$,[68] is more commonly measured.[10]

PRESSURE–TIME PRODUCT

PTP is usually calculated from the oesophageal pressure–time integral during inspiration. In mechanically ventilated patients the oesophageal pressure during assisted breathing is compared with that during a controlled breath, or that pressure calculated from the chest wall elastance and lung volume.[10] However, the early correlation of $\dot{V}O_{2\,resp}$ with PTP used the transdiaphragmatic pressure in spontaneously breathing subjects.[65] Using either technique, importantly, the effort expended before $\dot{V}$ occurs due to $PEEP_i$ is measured, probably accounting for the better correlation of $\dot{V}O_{2\,resp}$ with PTP than W_B.[65] Although incremental pressure support ventilation may reduce PTP in COPD patients, the effect can be variable with some patients also showing evidence of expiratory muscle activity due to delayed sensing of neural expiration.[10]

Imaging the chest

Simon PG Padley

RADIOLOGICAL TECHNIQUES

Of the imaging techniques available for investigating patients in the intensive care unit (ICU), the chest radiograph remains the most important, with ultrasound being utilised in a selected group of patients. High-resolution and spiral computed tomography (CT) allow further investigation of these patients in certain situations.

CONVENTIONAL CHEST RADIOGRAPHY

Because of the advent of modern PACS (picture archiving and communication systems), digital chest radiographs are now readily available in the ICU shortly after acquisition, and may be compared with previous radiographs using multi-monitor display workstations. The views of the chest most frequently performed in the ambulant patient are the erect postero-anterior (PA) and lateral projections, taken with the patient breath-holding at total lung capacity. While portable or mobile chest radiography, as undertaken on an ICU, has the obvious advantage that the examination can be done without moving the patient from the ward, there are many disadvantages. These include:

- shorter focus–film distance causing magnification
- limited X-ray output necessitating long exposure times with resultant movement blurring
- difficulties with satisfactory patient positioning.

DIGITAL CHEST RADIOLOGY

In the ICU, digital chest radiographs may be obtained utilising conventional X-ray generators, but the image is acquired on a reusable capture. The digital information is then manipulated, displayed and stored in whatever format is desired. Digital radiographic systems are able to capture and display a standard-density image from a much wider range of exposures (**Fig. 39.1**).

COMPUTED TOMOGRAPHY

CT relies on differing absorption of X-rays by tissues with constituents of differing atomic number, so slight differences in X-ray absorption can be interpreted to produce a cross-sectional image. The components of a CT scanner are an X-ray tube, which rotates around the patient, and an array of X-ray detectors opposite the tube. The speed with which a CT scanner acquires an image depends upon the time it takes to rotate the anode around the patient. Modern CT machines have tube rotation times of as little as 0.25 seconds.

Spiral (also known as volume or helical) scanning entails sustained patient exposure by the rotating X-ray tube during continuous movement of the examination couch through the CT gantry aperture. In this way a continuous data set or 'spiral' of information may be acquired in a single breath-hold. The information is reconstructed into axial sections, perpendicular to the long axis of the patient, identical to conventional CT sections. Three-dimensional reconstructions of complex anatomical areas can also be produced.

When short rotation times are coupled with the ability to acquire multiple spirals simultaneously (currently up to 320 detector rows), the speed of these systems becomes so great that breath-holding or suspended ventilation is no longer necessary for high-quality imaging. Furthermore, the detector thickness that determines the minimum slice width of the reconstructed images is now commonly less than 1 mm.

INTRAVENOUS CONTRAST ENHANCEMENT

The inherent high contrast on CT between vessels and surrounding air in the lung, and vessels and surrounding fat within the mediastinum reduces the need for intravenous contrast enhancement in most instances. However, in some circumstances, for example to aid the distinction between hilar vessels and a soft-tissue mass or to detect a pulmonary artery embolus, contrast is required. The timing of the injection of contrast media depends on the technical attributes of the CT scanner. Rapid scanning protocols with automated injectors tend to improve contrast enhancement of vascular structures at the expense of enhancement of solid lesions because of the rapidity of scanning. With spiral CT, it is possible to achieve good opacification of all the thoracic vascular structures with small volumes of contrast media. Optimal contrast enhancement of the pulmonary arteries occurs 10–15 seconds after the start of contrast injection, usually at 5 mL/s by a power injector. Timing of image acquisition is vital for accurate

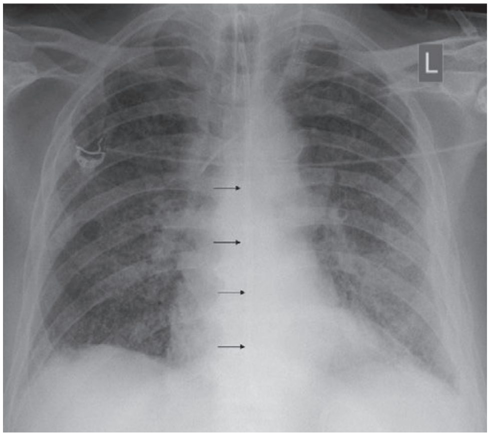

Figure 39.1 Digital radiograph. There is an endotracheal tube, a left internal jugular vein line and a nasogastric tube (arrows).

diagnosis of pulmonary embolism. However, when examining inflammatory lesions such as the reaction around an empyema, it may be necessary to delay scanning by 60 seconds to allow contrast to diffuse into the extravascular space.

HIGH-RESOLUTION COMPUTED TOMOGRAPHY (HRCT)

Narrow collimation images of the lung correlate closely with the macroscopic appearances of pathological specimens. In diffuse lung disease, HRCT allows a substantial improvement in diagnostic accuracy compared with chest radiography. Narrow-section images can be acquired either as part of a volumetric acquisition or as interspaced images, usually 1.5 mm thickness, obtained every 1 cm. The radiation burden to the patient of this interspace or sequential technique is considerably less than with volumetric scanning – typically by a factor of 10 times.

CLINICAL APPLICATIONS OF HRCT IN THE ICU PATIENT

HRCT is increasingly being used to confirm the impression of an abnormality seen on a chest radiograph. HRCT may also be used to achieve a histospecific diagnosis in some patients with obvious but non-specific radiographic abnormalities. Furthermore, HRCT has provided a number of useful insights into chest disease in the severely ill patient in an ICU setting.

HRCT in uncomplicated acute respiratory distress syndrome (ARDS)[1]

- HRCT reveals that the apparently homogeneous opacification apparent on the chest radiograph has an anterior-to-posterior graded increase in density – an appearance referred to as a gravitational gradient (**Fig. 39.2**).

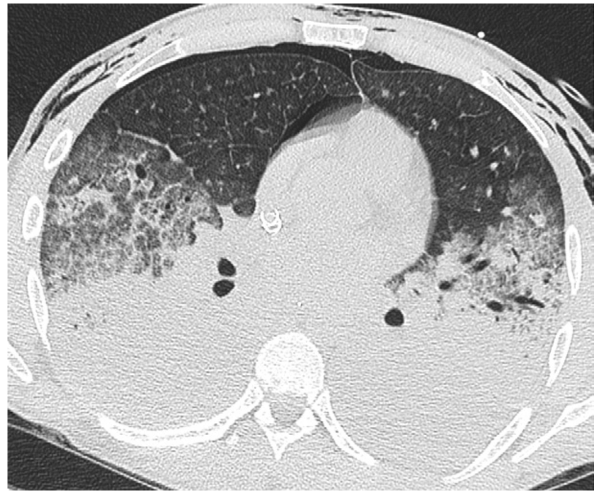

Figure 39.2 Computed tomography of a patient with acute respiratory distress syndrome. Note the marked anterior to posterior density gradient. The anterior lung is of almost normal density, becoming of ground-glass attenuation in the mid part of the lung before fading into consolidation posteriorly. There are small pneumothoraces bilaterally and surgical emphysema.

- HRCT demonstrates early dilatation of the smaller airways within areas of ground-glass density, an appearance that suggests development of fibrosis, and may prompt anti-inflammatory treatment.
- HRCT demonstrates that a shift from the supine to the prone position results in redistribution of the previously dependent dense parenchymal opacification to the now dependent anterior lung, a phenomenon that may be accompanied by improvements in patient oxygenation.

HRCT of complications of ARDS[2,3]

- Infection is common in ARDS. Diagnosis may be difficult. Radiographically there may be a lack of specific findings, often due to superimposition of changes attributable to ARDS. This is a particular problem in the critically ill patient when the usual indicators of pneumonia are also unreliable. Although the diagnosis may still be in question following HRCT, associated pneumonic changes such as abscess formation, empyema and mediastinal disease, as well as development of non-dependent areas of consolidation, are all useful pointers to superadded infection (see Fig. 39.2).
- Barotrauma – mediastinal and interstitial emphysema, as well as pneumothorax, are all increasingly common at higher levels of peak end-expiratory pressure (PEEP). The incidence of barotrauma has been reported to be as high as 50%.
- HRCT allows the exact location of loculated air collections to be defined.

NORMAL RADIOGRAPHIC ANATOMY

THE MEDIASTINUM, CENTRAL AIRWAYS AND HILAR STRUCTURES

Appreciation of abnormality requires a sound grasp of normal radiological anatomy. The mediastinum is delimited by the lungs on each side, the thoracic inlet above, the diaphragm below and the vertebral column posteriorly. Because the various structures that make up the mediastinum are superimposed on each other on the chest radiograph, they cannot be separately identified. Nevertheless, because a chest radiograph is usually the first imaging investigation, it is necessary to have an appreciation of the normal appearances of the mediastinum, together with variations due to the patient's body habitus and age. Key points include:

- Only the outline of the mediastinum and the air-containing trachea and bronchi (and sometimes oesophagus) are clearly seen on a normal chest radiograph.
- The right superior mediastinal border is formed by the right brachiocephalic vein and superior vena cava, and becomes less distinct as it reaches the thoracic inlet. The right side of the superior mediastinum can appear to be considerably widened in patients with an abundance of mediastinal fat.
- The left mediastinal border above the aortic arch is the result of summation of the left carotid and left subclavian arteries together with the left brachiocephalic and jugular veins.
- The left cardiac border comprises the left atrial appendage, which merges inferiorly with the left ventricle. The silhouette of the heart should always be sharply outlined. Any blurring of the border is due to loss of immediately adjacent aerated lung, usually by collapse or consolidation.
- The density of the heart shadow to the left and right of the vertebral column should be identical and any difference indicates pathology (e.g. an area of consolidation or a mass in a lower lobe).
- The trachea and main bronchi should be visible through the upper and middle mediastinum.
- In older individuals, the trachea may be displaced by a dilated aortic arch. In approximately 60% of normal subjects, the right wall of the trachea (the right paratracheal stripe) can be identified as a line of uniform thickness (less than 4 mm in width); when it is visible it excludes the presence of an adjacent space-occupying lesion, most usually lymphadenopathy.
- The carinal angle is usually less than 80°. Splaying of the carina is an insensitive sign of subcarinal disease, either in the form of massive subcarinal lymphadenopathy, or a markedly enlarged left atrium.
- The origins of the lobar bronchi, where they are projected over the mediastinal shadow, can usually be identified but the segmental bronchi within the lungs are not generally seen on plain radiography.
- Normal hilar shadows on a chest radiograph represent the summation of the pulmonary arteries and veins.
- The hila are approximately the same size and the left hilum normally lies between 0.5 cm and 1.5 cm above the level of the right hilum. The size and shape of the hila show remarkable variation in normal individuals, making subtle abnormalities difficult to identify.

THE PULMONARY FISSURES, VESSELS AND BRONCHI

The two lungs are separated by the four layers of pleura behind and in front of the mediastinum. The resulting posterior and anterior junction lines are often visible on chest radiographs as nearly vertical stripes, the posterior junction line lying higher than the anterior. The junction lines are not invariably seen and their presence or absence is not usually of significance (**Fig. 39.3**).

The upper and lower lobes of the left lung are separated by the major (or oblique) fissure. The upper, middle and lower lobes of the right lung are separated by the major fissure and the minor (horizontal or transverse) fissure. The minor fissure is visible in over half of normal PA chest radiographs. The major fissures are not visible on a frontal radiograph and are inconstantly identifiable on lateral radiographs. In a few individuals, fissures are incompletely developed – a point familiar to thoracic surgeons performing a lobectomy, because of incomplete cleavage between lobes. Accessory fissures are occasionally seen.

All of the branching structures seen within normal lungs on a chest radiograph represent pulmonary arteries or veins. It is often impossible to distinguish arteries from veins in the lung periphery. On a chest radiograph taken in the erect position, there is a gradual increase in the diameter of the vessels, at equidistant points from the hilum, travelling from lung apex to base; this gravity-dependent effect disappears if the patient is supine or in cardiac failure.

THE DIAPHRAGM AND THORACIC CAGE

The interface between aerated lung and the diaphragm is sharp and the highest point of each dome is normally medial to the midclavicular line. The right dome of the diaphragm is higher than the left by up to 2 cm in the erect position unless the left dome is elevated by air in the stomach (**Fig. 39.4**).

Filling-in or blunting of these costophrenic angles usually represents pleural disease, either pleural thickening or an effusion.

POSITIONING OF TUBES AND LINES

CENTRAL VENOUS CATHETERS (CVC)

The end of a CVC needs to be intrathoracic, and is ideally in the superior vena cava. CVCs may be introduced via

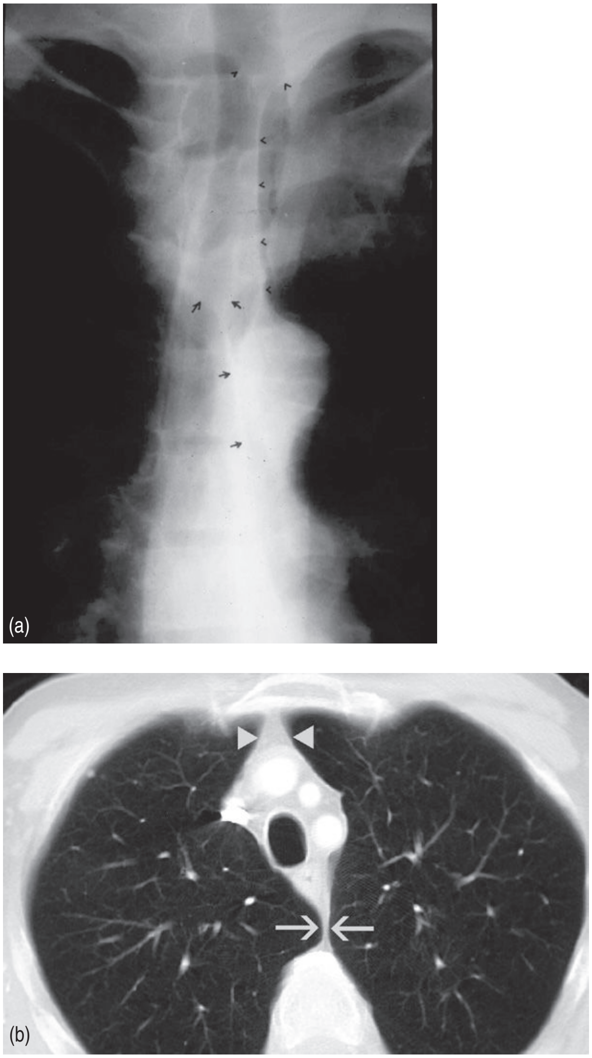

Figure 39.3 (a) Close-up of the mediastinum of a patient in whom both the anterior and posterior junction lines are evident. The anterior junction line is more inferior and slants from right to left (short arrows), whereas the posterior junction line is more vertical, superior and is delineated by the arrowheads. (b) Computed tomography scan through the upper mediastinum demonstrating the anterior (arrowheads) and posterior (arrows) junction lines in a different patient.

an antecubital, subclavian or jugular vein. Subclavian venous puncture carries a risk of pneumothorax and mediastinal haematoma. Rarely, perforation of the subclavian vein leads to fluid collecting in the mediastinum or pleura. All catheters have a potential risk of coiling, misplacement, knotting and fracture (**Fig. 39.5**). The tip should not abut the vessel wall at an obtuse angle.

PULMONARY ARTERY FLOTATION CATHETERS

Ideally the end of the catheter should be maintained less than 5–8 cm (2–3 inches) beyond the bifurcation of the main pulmonary artery in either the right or left pulmonary artery (see Fig. 39.5). When the pulmonary artery occlusion pressure is measured, the balloon is inflated, and the flow of blood carries the catheter tip peripherally, to an occluded position. After the measurement has been made the balloon is deflated and the catheter returns to a central position; otherwise there is a risk of pulmonary infarction. The inflation balloon is radiolucent. The balloon should normally be kept deflated.

Figure 39.4 Erect chest radiograph of a patient with a pneumoperitoneum demonstrating the normal thickness in position of the hemidiaphragms. The right lies slightly higher than the left.

NASOGASTRIC TUBES

These should reach the stomach but may coil in the oesophagus or occasionally are inserted into the tracheobronchial tree (**Fig. 39.6**).

ENDOTRACHEAL TUBES

Extension and flexion of the neck may make the tip of an endotracheal tube move by as much as 5 cm. With the neck in neutral position the tip of the tube should ideally be about 4–5 cm above the carina. A tube that is inserted too far usually passes into the right bronchus, with the risk of non-ventilation or collapse of the left lung (**Fig. 39.7**).

TRACHEOSTOMY TUBES

The tube tip should be situated centrally in the airway at the level of T_3. Acute complications of tracheostomy include pneumothorax, pneumomediastinum and

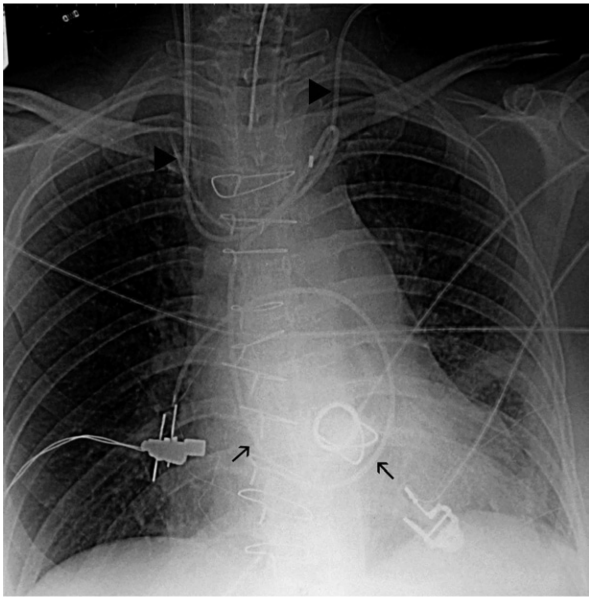

Figure 39.5 Intensive care unit patient with multiple tubes and lines in place. The endotracheal tube tip position is satisfactory, and there are sternotomy wires, an intra-aortic balloon pump (radiopaque tip) and a prosthetic heart valve. The central line inserted into the left internal jugular vein passes into the right internal jugular vein. The Swan–Ganz catheter, which has been inserted via the right internal jugular vein, loops into the left brachiocephalic vein, before taking a satisfactory course through the cardiac chambers (black arrows).

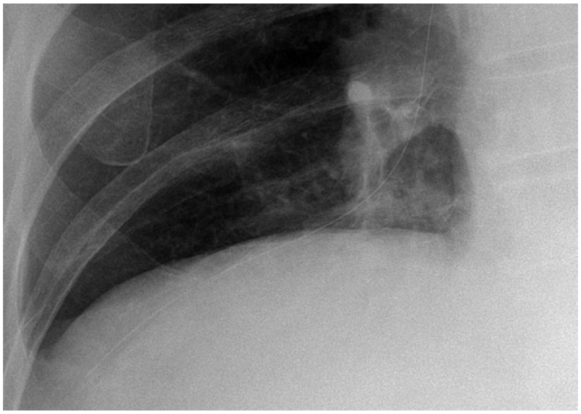

Figure 39.6 Misplaced nasogastric tube.

subcutaneous emphysema. Long-term complications include tracheal ulceration, stenosis and perforation.

PLEURAL TUBES

These are used to treat pleural effusions and pneumothoraces. A radiopaque line usually runs along pleural tubes, and is interrupted where there are side holes. It

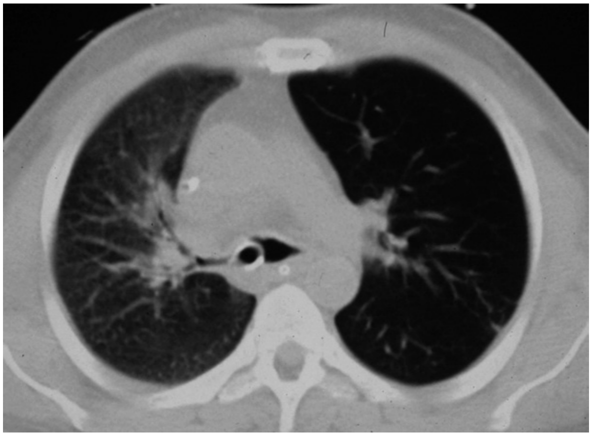

Figure 39.7 Endotracheal tube inserted into the right main bronchus as demonstrated on computed tomography. This image, obtained in expiration, demonstrates air trapping in the left lung.

Figure 39.8 Computed tomography scan demonstrating bilateral pneumothoraces in a patient with acute respiratory distress syndrome. Note is made of bilateral chest drains.

is important to check that all the side holes are within the thorax. Tracks may remain on the chest X-ray following removal of chest tubes, causing tubular or ring shadows. When doubt remains about tube position, then CT scanning should be considered (Fig. 39.8).

MEDIASTINAL DRAINS

These are usually present following sternotomy. Apart from their position, they look like pleural tubes.

INTRA-AORTIC BALLOON PUMP

These are used in patients with cardiogenic shock, often following cardiac surgery. The ideal position of the

catheter tip is just distal to the origin of the left subclavian artery (**Fig. 39.9**). If the catheter tip is advanced too far it may occlude the left subclavian artery, and if it is too distal the balloon may occlude branches of the abdominal aorta. The intra-aortic balloon pump may be visible only by its radiopaque tip (see Fig. 39.9).

PACEMAKERS

These may be permanent or temporary (**Fig. 39.10**). Temporary epicardial wires are sometimes inserted during cardiac surgery, and may be seen as thin, almost hair-like metallic opacities overlying the heart. Temporary pacing electrodes are usually inserted transvenously via a subclavian or jugular vein. If a patient is not being paced properly, a chest radiograph may reveal that the position of the electrode tip is unstable, or that a fracture in the wire has occurred.

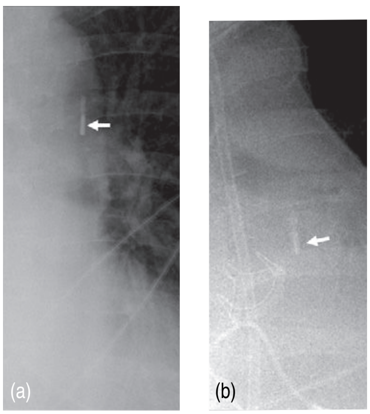

Figure 39.9 Intra-aortic balloon pump. Two chest radiographs demonstrating the tip of the balloon pump: (a) just distal to the origin of the left subclavian artery (arrow), and (b) further down the descending thoracic aorta (arrow).

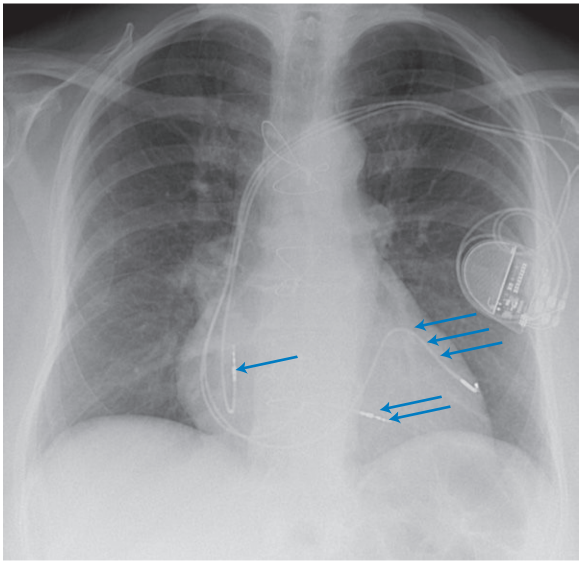

Figure 39.10 Biventricular pacemaker. Note the right atrial lead (arrow), right ventricular lead (double arrows) and coronary sinus lead (triple arrows).

RADIOGRAPHIC SIGNS OF PATHOLOGY

CONSOLIDATION

Consolidation, or synonymously air space shadowing, is due to opacification of the air-containing spaces of the lung, usually without a change in volume of the affected area. It is not possible to tell what the air space filling is due to in the absence of a clinical history, except perhaps for shadowing due to cardiogenic alveolar oedema, when there will be associated signs of cardiac failure. Typical features of all forms of consolidation (**Fig. 39.11**) include:

- ill-defined margins, except where it directly abuts a pleural surface
- sharply demarcated by fissures
- loss of vascular markings
- air bronchograms – the bronchi, usually invisible, may become apparent in negative contrast to the air space opacification
- acinar opacities, due to individual acini or secondary pulmonary lobules being opacified but still surrounded by normally aerated lung, usually seen at

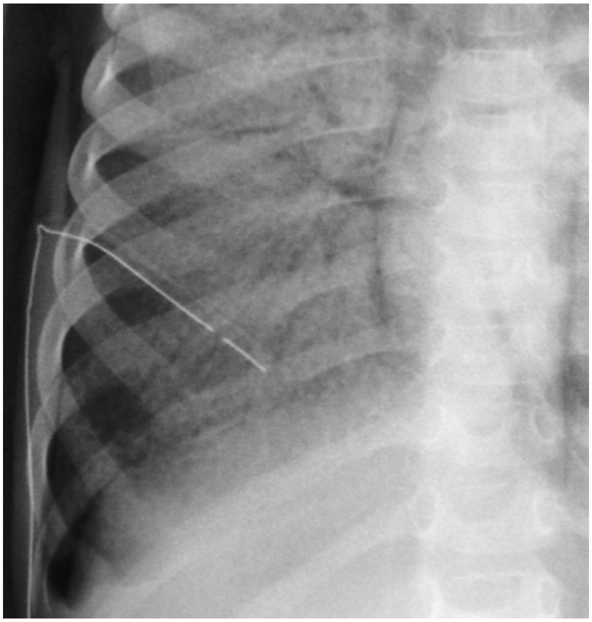

Figure 39.11 Close-up view of an area of consolidation adjacent to the right heart border, which is obscured. Air bronchograms can be identified passing through this area. A chest tube is in situ.

the periphery of a more confluent area of consolidation, and 0.5–1 cm in diameter

- ground-glass opacification, when consolidation has caused only partial filling of the air spaces
- silhouette sign – consolidation abutting a soft-tissue structure causes the silhouette of that structure to be lost.

When an area of consolidation undergoes necrosis, due to either infection or infarction, then liquefaction may result, and if there is either a gas-forming organism or communication with the bronchial tree then an air–fluid level may develop in addition to cavity formation.

COLLAPSE

When there is partial or complete volume loss in a lung or lobe this is referred to as collapse or atelectasis, implying a diminished volume of air in the lung with associated reduction of lung volume. There are several different mechanisms for lung or lobar collapse, for example relaxation or passive collapse, when fluid or air accumulates in the pleural space, cicatrisation collapse, when volume loss is associated with pulmonary fibrosis, adhesive collapse, as in ARDS, and resorption collapse, as in bronchial obstruction.

The radiographic appearance in pulmonary collapse depends upon a number of factors. These include the mechanism of collapse, the extent of collapse, the presence or absence of consolidation in the affected lung and the pre-existing state of the pleura. This latter factor includes the presence of underlying pleural tethering or thickening and the presence of pleural fluid.

The direct signs of collapse include:

- displacement of interlobar fissures
- loss of aeration resulting in increased density or the presence of the silhouette sign
- crowding of vessels and bronchi.

The indirect signs of collapse include:

- elevation of the hemidiaphragm, especially with lower lobe collapse
- mediastinal displacement, especially in upper lobe collapse
- hilar displacement, where the hilum is elevated in upper lobe collapse and depressed in lower lobe collapse
- compensatory hyperinflation of remaining normal lung, resulting in increased transradiancy or herniation across the midline from the normal side
- crowding of the ribs reflecting diminished overall volume of the affected hemithorax.

COMPLETE LUNG COLLAPSE

Complete collapse (**Fig. 39.12**) will cause complete opacification of the hemithorax, with displacement of the mediastinum to the affected side and elevation of the hemidiaphragm. Compensatory hyperinflation of the contralateral lung with herniation across the midline may be apparent. Herniation may occur in the retrosternal space, anterior to the ascending aorta, or may be posterior to the heart.

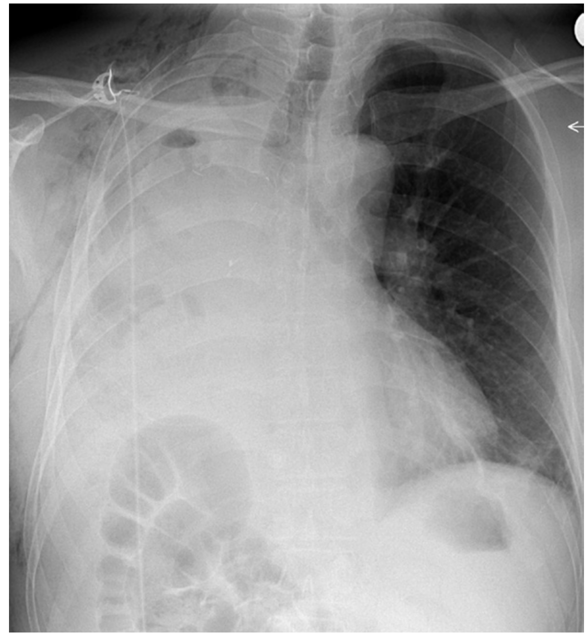

Figure 39.12 Complete lung collapse. There was an obstructing tumour in the right main bronchus. The right hemithorax is opaque, the mediastinum has shifted and the trachea is deviated to the right.

INDIVIDUAL OR COMBINED LOBAR COLLAPSE

In any situation, some or all of the signs may be present.

*Right upper lobe collapse (**Fig. 39.13**)*

- Horizontal fissure moves upwards and medially towards the superior mediastinum.
- Trachea deviates to the right.
- Compensatory hyperinflation of the right middle and lower lobes.

*Middle lobe collapse (**Fig. 39.14**)*

- Horizontal fissure and lower half of the oblique fissure move towards each other – best seen on the lateral projection.
- Frontal radiograph changes may be subtle, with obscuration of the right heart border.
- Indirect signs of volume loss are rarely obvious.

Right lower lobe collapse

- There is partial depression of the horizontal fissure.
- There is triangular opacity of the collapsed lower lobe on the frontal projection, usually obscuring the diaphragm but preserving the right heart border.

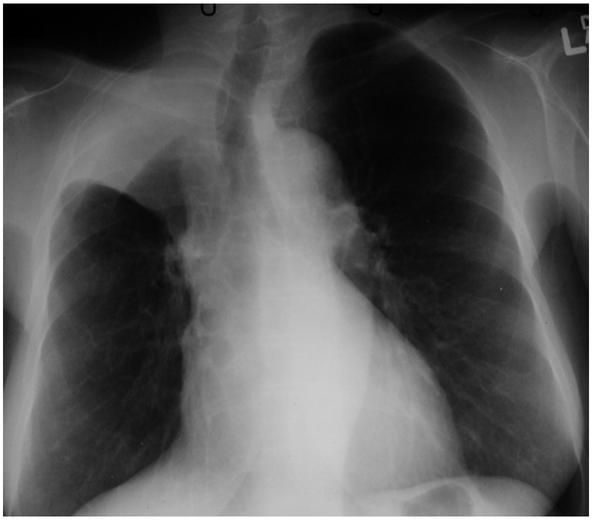

Figure 39.13 Right upper lobe collapse. The horizontal fissure has become elevated and the right upper lobe has become a wedge-shaped density extending from the hilum to the right lung apex. There is evidence of volume loss with shift of the trachea to the right side.

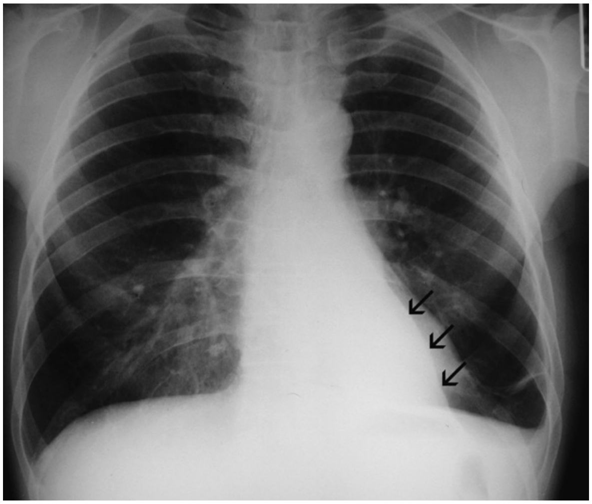

Figure 39.15 Left lower lobe collapse. The left lower lobe has become a wedge-shaped density behind the heart forming a double left heart border (arrows). The left hilar vessel to the lower lobe has disappeared as a result of collapse.

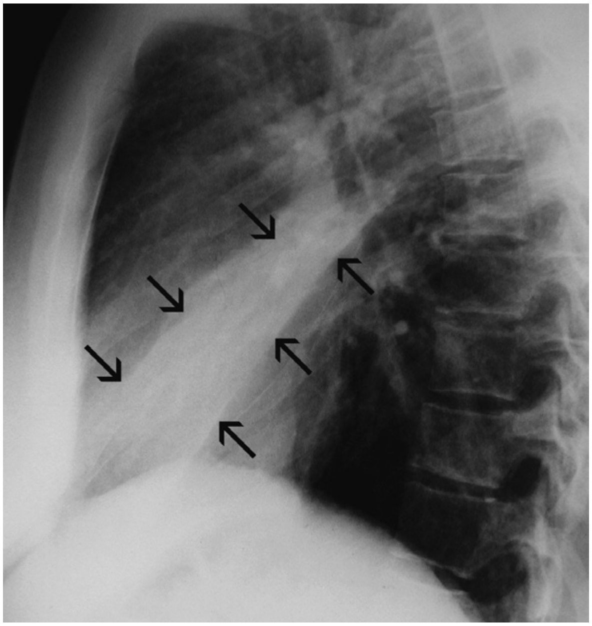

Figure 39.14 Middle lobe collapse. The horizontal fissure is depressed and demarcates the collapsed middle lobe as a wedge-shaped density best demonstrated on the lateral (arrows).

- Eventually a completely collapsed lower lobe may be so small that it flattens and merges with the mediastinum, producing a thin, wedge-shaped shadow.

Left lower lobe collapse (**Fig. 39.15**)

- Collapsed lobe may be obscured by the heart and a penetrated view may be required.
- Mediastinal structures and the diaphragm adjacent to the non-aerated lobe are obscured.
- Extreme volume loss may cause the lobe to be so small as to be invisible as a separate opacity.
- There is loss of lower lobe artery silhouette at the hilum.

Lingula collapse

- Is often involved in collapse of the left upper lobe.
- May collapse individually.
- Radiographic features are similar to those of middle lobe collapse.

Left upper lobe collapse (**Fig. 39.16**)

- Lateral view demonstrates anterior displacement of the entire oblique fissure, oriented almost parallel to the anterior chest wall, demarcating the posterior surface of the upper lobe as an elongated opacity extending from the apex almost reaching the diaphragm and lying anterior to the hilum.
- Eventually the upper lobe retracts posteriorly and loses contact with the anterior chest wall.

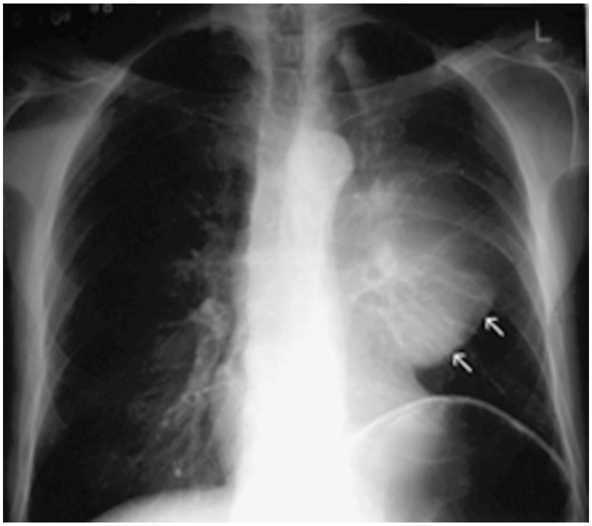

Figure 39.16 Left upper lobe collapse. A hazy opacity extends from the hilum towards the left lung apex. It is sharply demarcated inferiorly and laterally (white arrows) owing to the presence of a large tumour at the left hilum, which is obstructing the left upper lobe bronchus. Note the signs of volume loss, particularly the elevation of the left hemidiaphragm.

- Frontal radiograph demonstrates an ill-defined hazy opacity in the upper, mid and sometimes lower zones, with loss of hilar clarity.
- Hilum is often elevated, and the trachea deviated to the left.

COMBINED COLLAPSE

Right lower and middle lobe collapse is the most common pairing since a lesion may occur in the bronchus intermedius. The appearances are similar to right lower lobe collapse except that the horizontal fissure is not apparent, and the opacification reaches the lateral chest wall on the frontal radiograph, and similarly extends to the anterior chest wall on the lateral view.

Right upper and middle lobe collapse is much less common because of the distance between the origins of their bronchi, and can generally be taken to imply the presence of more than one lesion. This combination will produce appearances almost identical to those of left upper lobe collapse (see Fig. 39.16). On occasion isolated right upper lobe collapse will also produce appearances that are identical to left upper lobe collapse.

UNILATERAL INCREASED TRANSRADIANCY

The commonest causes are technical and include:

- patient rotation
- poor beam centring
- offset grid.

Pathological causes include:

- chest wall changes
- mastectomy
- congenital unilateral absence of pectoral muscles, known as Poland's syndrome
- reduced vascularity when interruption or significant reduction in the blood supply to one lung may cause that lung to be of increased transradiancy
- lung hyperexpansion due to air trapping or asymmetric emphysema.

When there is relative increased transradiancy of one hemithorax for which there is no obvious cause then the possibility of generalised increase in radiopacity of the opposite side should be considered – for example, the posterior layering of a pleural effusion in a supine patient. Usually hypertransradiancy due to technical factors can be identified by comparison of the soft tissues around the shoulder girdle, and particularly over the axillae.

ABNORMALITIES OF THE MEDIASTINUM

Pneumomediastinum or mediastinal emphysema is the presence of air between the tissue planes of the mediastinum (see section on Injuries to the mediastinum, below). Chest radiography may show vertical translucent streaks in the mediastinum, representing air separating the soft-tissue planes. The air may extend up into the neck and over the chest wall, causing subcutaneous emphysema, and also over the diaphragm. The mediastinal pleura may be displaced laterally and then be visible as a thin stripe alongside the mediastinum.

Acute mediastinitis is usually due to perforation of the oesophagus, pharynx or trachea and chest radiograph usually shows widening of the mediastinum and pneumomediastinum.

Mediastinal haemorrhage may occur from venous or arterial bleeding. The mediastinum appears widened, and blood may be seen tracking over the lung apices. It is imperative to identify a life-threatening cause such as aortic rupture.

Aortic dissection or aneurysmal dilatation may also cause widening of the mediastinal silhouette on chest radiography (**Fig. 39.17**).

PLEURAL FLUID

The most dependent recess of the pleural space is the posterior costophrenic angle and this is where a small effusion will tend to collect. As little as a few millilitres of fluid may be detected using decubitus views with a horizontal beam, ultrasound or CT. Larger volumes of fluid eventually fill in the costophrenic angle on the frontal view, and with increasing fluid a homogeneous opacity spreads upwards, obscuring the lung base (**Fig. 39.18**). The fluid usually demonstrates a concave upper edge, higher laterally than medially, and obscures the

Figure 39.17 Aortic dissection. Coronal computed tomographic image showing intimal flap in the descending aorta.

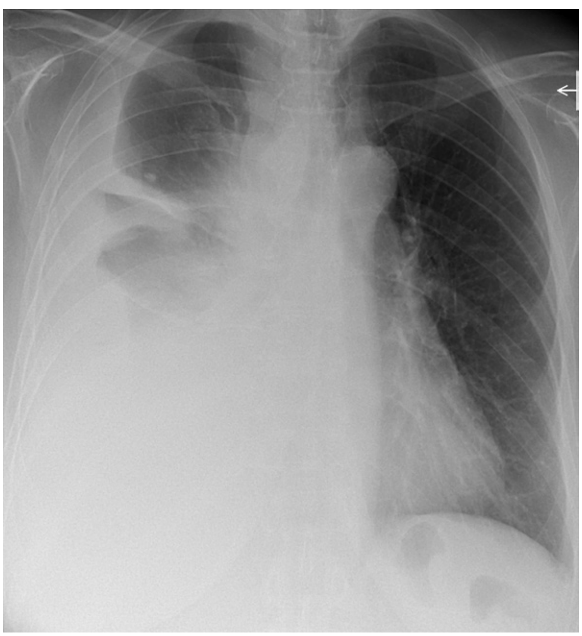

Figure 39.18 Large right pleural effusion. There is a typical configuration of the right upper border, a meniscus extending up the lateral chest wall.

diaphragm. Fluid may track into the fissures. A massive effusion may cause complete opacification of a hemithorax with passive atelectasis. The space-occupying effect of the effusion may push the mediastinum towards the opposite side, especially when the lung does not collapse significantly. Effusions in a supine patient redistribute into the paravertebral sulcus and produce an even increased density throughout that hemithorax.

Lamellar effusions are shallow collections between the lung surface and the visceral pleura, sometimes sparing the costophrenic angle, and occur early in heart failure.

Subpulmonary effusions accumulate between the diaphragm and undersurface of a lung, mimicking elevation of the hemidiaphragm, altering the diaphragmatic contour so the apex moves more laterally than usual. When left-sided, there is increased distance between the gastric air bubble and lung base.

Fluid may become loculated in the interlobar fissures and is most frequently seen in heart failure. Loculated interlobar effusions may disappear rapidly and are sometimes known as pulmonary pseudotumours.

Differentiation between a simple effusion and a complicated parapneumonic effusion or an empyema usually requires thoracentesis. Loculation is best demonstrated with ultrasound.

PNEUMOTHORAX

In an erect patient, air will usually collect at the apex (**Fig. 39.19**). The lung retracts towards the hilum and on a frontal chest film the sharp white line of the visceral pleura will be visible, separated from the chest wall by the radiolucent pleural space, which is devoid of lung markings. This should not be confused with a skin fold, which mostly occurs in supine or recumbent patients. The lung usually remains aerated, although perfusion is reduced in proportion to ventilation and therefore the radiodensity of the partially collapsed lung remains relatively normal. A large pneumothorax may lead to complete retraction of the lung, with some mediastinal shift towards the normal side. Since it is a medical emergency, tension pneumothorax is often treated before a chest radiograph is obtained. However, if a radiograph is taken in this situation it will show marked displacement of the mediastinum. Radiographically the lung may be squashed against the mediastinum, or herniate across the midline, and the ipsilateral hemidiaphragm may be depressed. A supine pneumothorax may produce increased transradiancy towards the diaphragm, and a deep sulcus sign.

COMPLICATIONS OF PNEUMOTHORAX

Pleural adhesions may limit the distribution of a pneumothorax and result in a loculated or encysted pneumothorax (see Fig. 39.8). The usual appearance is an ovoid air collection adjacent to the chest wall, and it may be radiographically indistinguishable from a thin-walled subpleural pulmonary cyst or bulla. Pleural adhesions are occasionally seen as line shadows stretching between the two pleural layers, preventing relaxation of the underlying lung. Rupture of an adhesion

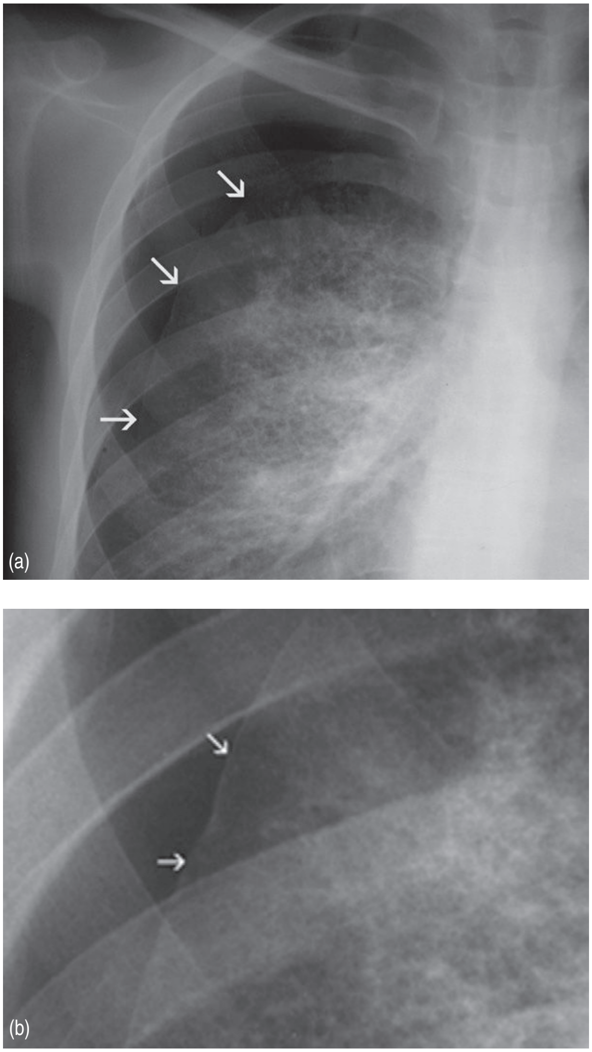

Figure 39.19 Pneumothorax. (a) This patient, with underlying lung abnormality, has developed a pneumothorax. The fine white line that represents the visceral pleura delineates the edge of the lung. (b) Close-up of the pleural line. Note how there are no vascular markings beyond this point.

may produce a haemopneumothorax. Collapse or consolidation of a lobe or lung in association with a pneumothorax is important because it may delay re-expansion of the lung.

Since the normal pleural space contains a small volume of fluid, blunting of the costophrenic angle by a short fluid level is commonly seen in a pneumothorax. In a small pneumothorax this fluid level may be the most obvious radiological sign. A larger fluid level usually signifies a complication and represents exudate, pus or blood, depending on the aetiology of the pneumothorax. A hydropneumothorax is a pneumothorax containing a significant amount of fluid (**Fig. 39.20**). On

Figure 39.20 Hydropneumothorax developing in a patient who has had a previous pneumonectomy on the right for carcinoma. Spontaneous development of a bronchopleural fistula has occurred.

a radiograph obtained with a horizontal beam, a fluid level is evident. A hydro- or pyopneumothorax may arise as a result of a bronchopleural fistula, and may be a complication of surgery, tumour or infection.

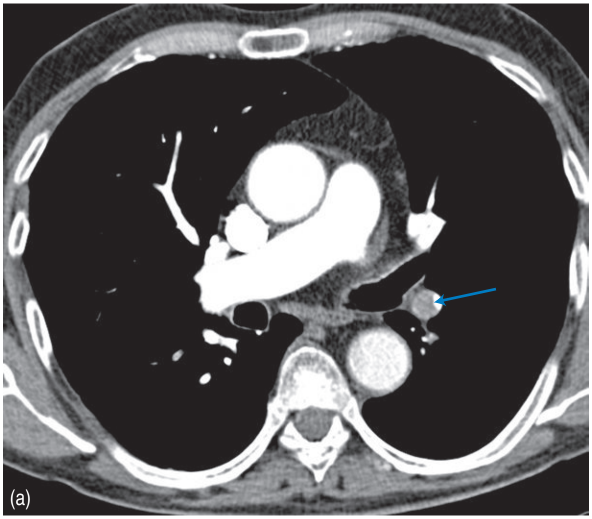
PULMONARY EMBOLISM

CT diagnosis of pulmonary embolism is becoming routinely available, and depends upon the ability to acquire, within a single breath-hold, a volume of data large enough to include the entire thorax. This rapid acquisition allows excellent contrast opacification of the pulmonary arterial tree for the duration of the scan, revealing any thrombus within the central pulmonary vessels (**Fig. 39.21**). There are numerous studies evaluating helical and electron beam CT in the diagnosis of acute pulmonary embolus, with excellent reported sensitivity and specificity for the detection of clot down to the segmental level.[5–8] Most of these studies also allow other diagnoses to be made that explain the symptoms of chest pain or dyspnoea, even when no pulmonary embolism is present.

TRAUMA AND THE ICU PATIENT

SKELETAL INJURY[9]

Following trauma, rib fractures are common and may be single, multiple, unilateral or bilateral. In cases of chest trauma, the chest X-ray is more important in detecting a complication of rib fracture than the fracture



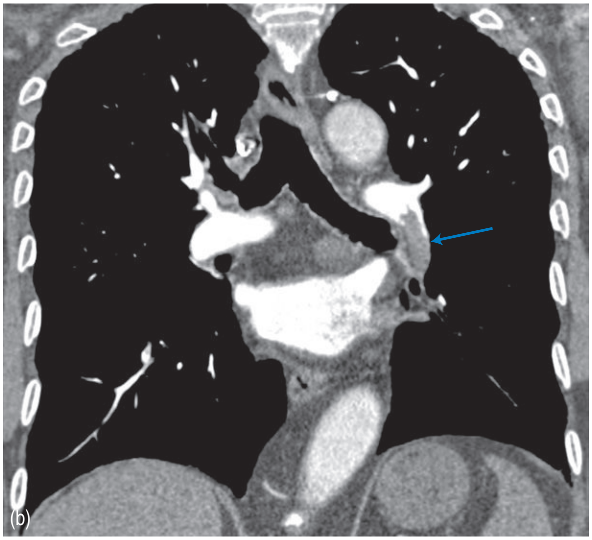


Figure 39.21 Pulmonary embolism: (a) axial and (b) coronal computed tomographic image of an embolus in the left lower lobe pulmonary artery (arrows).

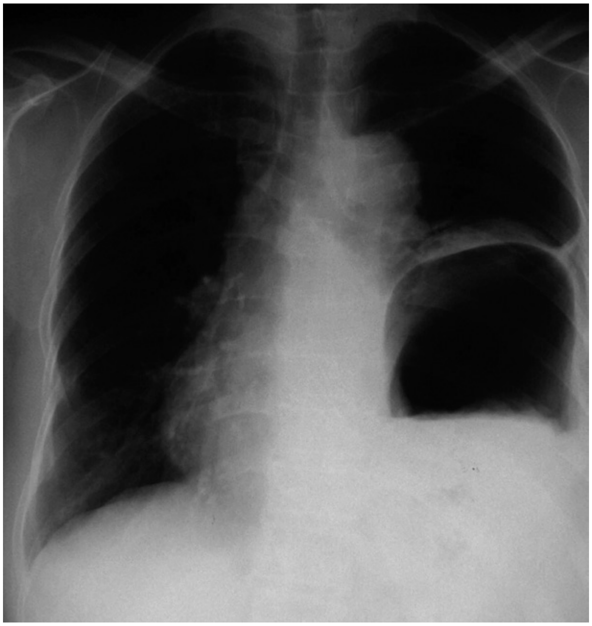

Figure 39.22 Ruptured left hemidiaphragm. Previous trauma resulted in rupture of the hemidiaphragm. A chest radiograph obtained some months later demonstrates herniation of the stomach into the left hemithorax.

itself. Fracture of one of the first three ribs is often associated with major intrathoracic injury, and fracture of the lower three ribs may be associated with important hepatic, splenic or renal injury. Complications of rib fracture include a flail segment, pneumothorax, haemothorax and subcutaneous emphysema. A flail segment is usually apparent clinically and radiologically. The fractured ends of ribs may penetrate underlying pleura and lung and cause a pneumothorax, haemothorax, haemopneumothorax or intrapulmonary haemorrhage. Air may also escape into the chest wall and cause subcutaneous emphysema. Fractures of the sternum usually require a lateral film or CT for visualisation. Fractures of the thoracic spine may be associated with a paraspinal shadow, which represents haematoma. Fractures of the clavicle may be associated with injury to the subclavian vessels or brachial plexus, and posterior dislocation of the clavicle at the sternoclavicular joint may cause injury to the trachea, oesophagus, great vessels or nerves of the superior mediastinum.

DIAPHRAGMATIC INJURY[10]

Laceration of the diaphragm may result from penetrating or non-penetrating trauma to the chest or abdomen. Rupture of the left hemidiaphragm is encountered more frequently in clinical practice than rupture on the right (**Fig. 39.22**). The typical plain film appearance is of obscuration of the affected hemidiaphragm and increased shadowing in the ipsilateral hemithorax due to herniation of stomach, omentum, bowel or solid viscera, although such herniation may be delayed. Ultrasound may demonstrate diaphragmatic laceration and free fluid in both the pleura and peritoneum. Barium studies may be useful to confirm herniation of stomach or bowel into the chest.

PLEURAL INJURY[9,11]

Pneumothorax may be a complication of rib fracture, and is then usually associated with a haemothorax. If no ribs are fractured, pneumothorax is secondary to a

pneumomediastinum, pulmonary laceration or penetrating chest injury. Pneumothorax due to a penetrating injury is liable to develop increased pressure, resulting in a tension pneumothorax, which may require emergency decompression. Haemothorax may also occur with or without rib fractures, and is due to laceration of intercostal or pleural vessels. If a pneumothorax is also present a fluid level will be seen on a horizontal-beam film. Pleural effusion may also result from trauma. Open injuries to the pleura are prone to infection and development of an empyema.

INJURIES TO THE LUNG[9,11,12]

Pulmonary contusion is due to haemorrhagic exudation into the alveoli and interstitial spaces and appears as patchy, non-segmental consolidation within the first few hours of penetrating or non-penetrating trauma. There is usually improvement within 2 days and clearance within 3–4 days. Pulmonary lacerations may be obscured by pulmonary contusion, but, as this resolves, the laceration will become evident. If filled with blood it appears as a homogeneous round opacity, and if partly filled with blood it may show a fluid level (**Fig. 39.23**). Such pulmonary haematomas or blood cysts gradually decrease in size, but may take a few months to resolve completely. Fat embolism is a rare complication of multiple fractures, with poorly defined nodular opacities throughout both lungs, which resolve within a few days.

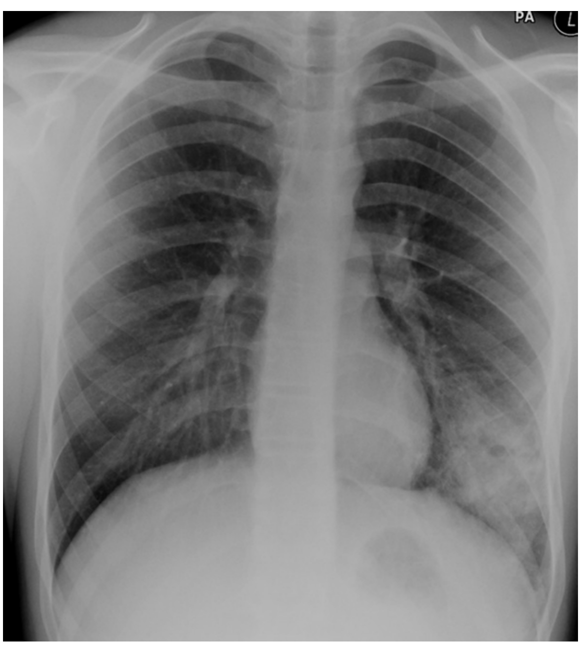

Figure 39.23 Pulmonary contusion. Left lower lobe air space opacity with a small amount of air within.

INJURIES TO THE TRACHEA AND BRONCHI[12,13]

Laceration or rupture of a major airway is an uncommon result of severe chest trauma. Fracture of the first three ribs and mediastinal emphysema and pneumothorax may also be evident. The injury is usually in the trachea just above the carina, or in a main bronchus just distal to the carina. If the bronchial sheath is preserved there may be no immediate signs or symptoms, but tracheostenosis or bronchiectasis may occur later. CT may be helpful in diagnosis, but bronchoscopy is the best diagnostic method in the acute stage.

INJURIES TO THE MEDIASTINUM[14]

Pneumomediastinum and mediastinal emphysema, discussed above, are the presence of air between the tissue planes of the mediastinum. Air may reach here as a result of pulmonary interstitial emphysema, perforation of the oesophagus, trachea or bronchus, or from a penetrating chest injury. Pulmonary interstitial emphysema is a result of alveolar wall rupture due to high intra-alveolar pressure, and may occur during violent coughing, severe asthma or crush injuries, or be due to positive-pressure ventilation. Air dissects centrally along the perivascular sheath to reach the mediastinum. Rarely, air may dissect into the mediastinum from a pneumoperitoneum. A pneumomediastinum may extend beyond the thoracic inlet into the neck, and over the chest wall. Pneumothorax is a common complication of pneumomediastinum, but the converse rarely occurs. Pneumomediastinum usually produces vertical translucent streaks in the mediastinum. This represents gas separating and outlining the soft-tissue planes and structures of the mediastinum. Gas shadows may extend up into the neck, or dissect extrapleurally over the diaphragm, or extend into the soft-tissue planes of the chest wall, causing subcutaneous emphysema. The mediastinal pleura may be displaced laterally, and become visible as a linear soft-tissue shadow parallel to the mediastinum. If mediastinal air collects beneath the pericardium the central part of the diaphragm may be visible, producing the ‘continuous diaphragm’ sign. Mediastinal haemorrhage may result from penetrating or non-penetrating trauma, and be due to venous or arterial bleeding. Many cases are probably unrecognised, as clinical and radiographic signs are absent. Important causes include automobile accidents, aortic rupture and dissection, and introduction of CVCs. There is usually bilateral mediastinal widening, but a localised haematoma may occur.

ACUTE AORTIC INJURY

Aortic rupture (**Fig. 39.24**)[15] is usually the result of an automobile accident. Most non-fatal aortic tears occur at the aortic isthmus, the site of the ligamentum arteriosum. Only 10–20% of patients survive the acute episode,

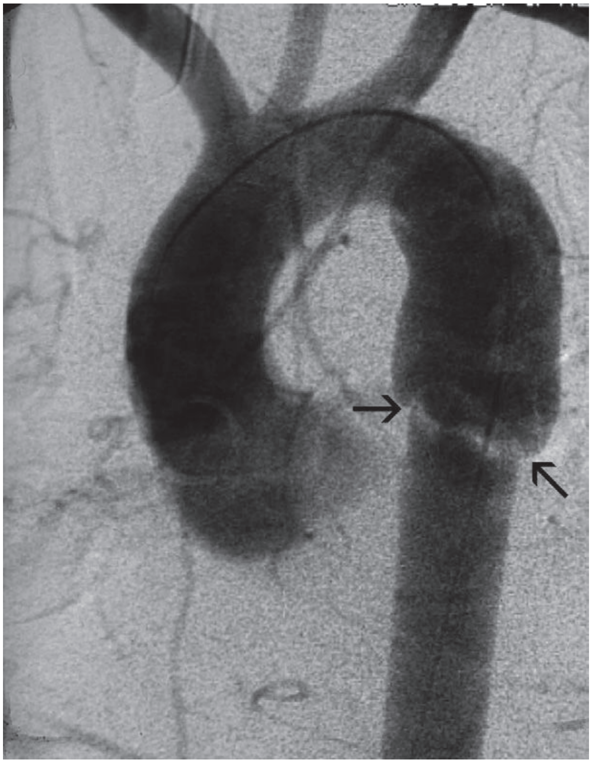

Figure 39.24 Arch aortogram demonstrating widening of the descending thoracic aorta due to aortic wall rupture. The point of return to normal calibre is demarcated by the arrows.

but a small number may develop a chronic aneurysm at the site of the tear. The commonest acute radiographic signs are widening of the superior mediastinum, and obscuration of the aortic knuckle. Other radiographic signs include deviation of the left main bronchus anteriorly, inferiorly and to the right, and rightward displacement of the trachea, a nasogastric tube or the right parasternal line. A left apical extrapleural cap or a left haemothorax may be visible. Although aortography is the definitive investigation, CT, transoesophageal echocardiography or magnetic resonance imaging may be diagnostic. In everyday practice, many departments will have emergency access to a CT scanner, but will not be centres of cardiothoracic surgery. A properly conducted CT scan demonstrating a normal mediastinum has a very high negative predictive value for aortic rupture. However, if CT is equivocal or shows a mediastinal haematoma then generally angiography will be required prior to surgery.

CARDIAC INJURY[16]

This is rare but may result from penetrating or blunt trauma. Penetrating injuries are usually rapidly fatal but may cause tamponade, ventricular aneurysm or septal defects. Blunt trauma may cause myocardial contusion and infarction and may be associated with transient or more permanent rhythm disturbance.

OESOPHAGEAL RUPTURE[17]

This is usually the result of instrumentation or surgery, but occasionally occurs in penetrating trauma, and is rarely spontaneous and due to sudden increase of intraoesophageal pressure (Boerhaave syndrome). Clinically there is acute mediastinitis; radiographically there are signs of pneumomediastinum, with or without a pneumothorax or hydropneumothorax, which is usually left-sided. The diagnosis should be confirmed by a swallow. This should initially be with water-soluble contrast medium in order to avoid the small risk of granuloma formation in the mediastinum that has been described following barium leakage. Chylothorax due to damage to the thoracic duct may become apparent hours or days after trauma. Thoracic surgery is the commonest cause.

THE POSTOPERATIVE CHEST

THORACIC COMPLICATIONS OF GENERAL SURGERY

ATELECTASIS

Atelectasis is the commonest pulmonary complication of thoracic or abdominal surgery. The chest X-ray usually shows elevation of the diaphragm, due to a poor inspiration. Linear opacities are present in the lower zones, and represent a combination of subsegmental volume loss and consolidation. The shadows usually appear about 24 hours postoperatively and resolve within 2–3 days.

PLEURAL EFFUSIONS

Pleural effusions are common immediately following abdominal surgery and usually resolve within 2 weeks. They may be associated with pulmonary infarction. Effusions due to subphrenic infection usually occur later.

PNEUMOTHORAX

Pneumothorax, when it complicates extrathoracic surgery, is usually a complication of positive-pressure ventilation or central venous line insertion. It may complicate nephrectomy.

ASPIRATION PNEUMONITIS

Aspiration pneumonitis is common during anaesthesia, but fortunately is usually insignificant. When significant, patchy consolidation appears within a few hours, usually basally or around the hila. Clearing occurs within a few days, unless there is superinfection.

PULMONARY OEDEMA

In the postoperative period, oedema may be cardiogenic or non-cardiogenic.

PNEUMONIA

Postoperative atelectasis and aspiration pneumonitis may be complicated by pneumonia. Postoperative pneumonias, therefore, tend to be associated with bilateral basal shadowing.

SUBPHRENIC ABSCESS

Subphrenic abscess usually produces elevation of the hemidiaphragm, pleural effusion and basal atelectasis. Loculated gas may be seen below the diaphragm, and fluoroscopy may show splinting of the diaphragm. Subphrenic abscess can be demonstrated by CT or ultrasound.

PULMONARY EMBOLISM

Pulmonary embolism may produce pulmonary shadowing, pleural effusion or elevation of the diaphragm, but is not excluded by a normal radiograph. In the ICU setting the radiological investigation of choice is spiral CT scanning.

THORACIC COMPLICATIONS OF CARDIAC SURGERY

Most cardiac operations are performed through a sternotomy incision, and wire sternal sutures are often seen on the postoperative films. Mitral valvotomy is now rarely performed via a thoracotomy incision, but this route is still used for surgery of coarctation of the aorta, patent ductus arteriosus, Blalock–Taussig shunts and pulmonary artery banding.

Widening of the cardiovascular silhouette is usual, and represents bleeding and oedema. Marked or progressive widening of the mediastinum suggests significant haemorrhage (**Fig. 39.25**). Some air commonly remains in the pericardium following cardiac surgery, so that the signs of pneumopericardium may be present.

Left basal shadowing is almost invariable, representing atelectasis. This shadowing usually resolves over a week or two. Small pleural effusions are also common in the immediate postoperative period.

Pneumoperitoneum is sometimes seen, due to involvement of the peritoneum by the sternotomy incision. It is of no pathological significance (see Fig. 39.4).

Violation of left or right pleural space may lead to a pneumothorax. Damage to a major lymphatic vessel may lead to a chylothorax or a more localised chyloma. Phrenic nerve damage may cause paresis or paralysis of a hemidiaphragm.

Surgical clips or other metallic markers have sometimes been used to mark the ends of coronary artery bypass grafts. Prosthetic heart valves are usually visible radiographically, but they may be difficult to see on an underpenetrated film.

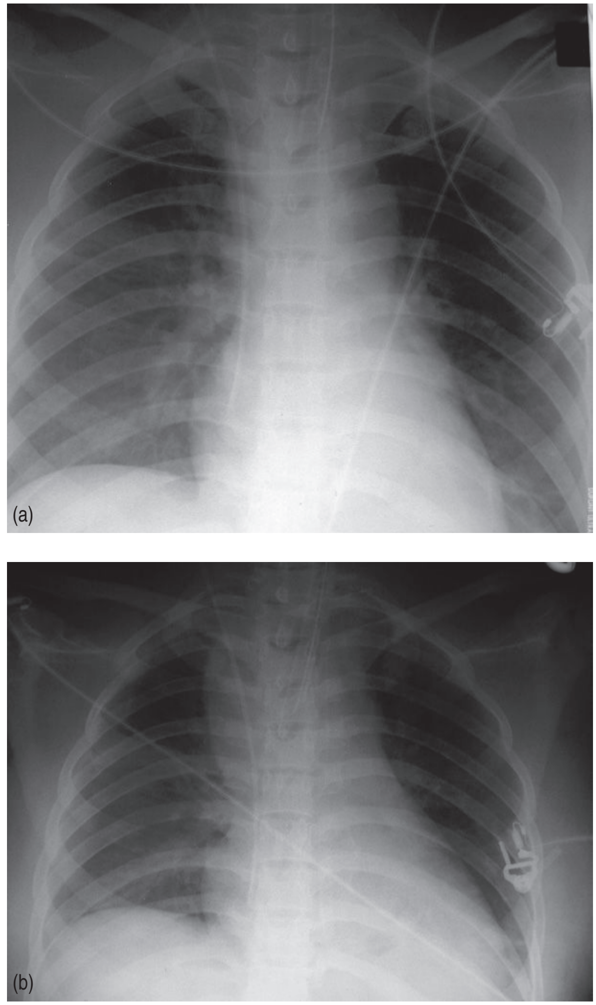

Figure 39.25 Following cardiac surgery (a) the postoperative chest radiograph appears satisfactory. A few hours later (b) the mediastinum has widened considerably, due to mediastinal haemorrhage.

Sternal dehiscence may be apparent radiographically by a linear lucency appearing in the sternum and alteration in position of the sternal sutures on consecutive films. The diagnosis is usually made clinically and may be associated with osteomyelitis. A first or second rib may be fractured when the sternum is spread apart. The importance of this observation is that it may explain chest pain in the postoperative period.

Acute mediastinitis may complicate mediastinal surgery, although it is more commonly associated with oesophageal perforation or surgery. Radiographically there may be mediastinal widening or pneumomediastinum, and these features are best assessed by CT scan.

Ultrasound in the ICU

Ubbo F Wiersema

Over the past decade point-of-care ultrasound has become an integral part of intensive care practice. An increasing number of clinical applications have been developed that facilitate time-critical therapeutic decision making and invasive diagnostic procedures. This chapter will describe ultrasound techniques that have an established role in intensive care, and are readily acquired with a short period of training. Acquisition of ultrasound proficiency is best achieved with a combination of theoretical learning (basic physics of ultrasound, relevant anatomy, image interpretation), direct supervision of image acquisition, and practice.[1,2]

EQUIPMENT

The ideal ultrasound machine for intensive care applications is compact, easily transportable and robust. The console should be waterproof and able to withstand repeated disinfection procedures. To avoid transmission of nosocomial skin flora between patients the transducer, console and electrocardiograph leads (if used) should be disinfected (e.g. with alcohol-based wipes) after each examination.[3,4] Single-use coupling gel should be used instead of multi-use bottles.

Different transducers (probes) are designed for different applications:

- A low-frequency (3–5 MHz) phased array transducer (transthoracic echocardiography transducer) is suitable for chest and abdominal ultrasound.
- A mid-frequency (5–8 MHz) microconvex curved array transducer is also suitable for chest ultrasound and is sometimes useful for subclavian vein ultrasound.
- A high-frequency (6–13 MHz) linear array transducer is necessary for vascular access and ocular ultrasound.
- A low-frequency (2–5 MHz), large-footprint, curved array transducer provides optimal abdominal ultrasound imaging, but is not essential.

CHEST ULTRASOUND

Ultrasound waves are unable to penetrate aerated lung tissue. Historically, this has limited ultrasound of the chest largely to the evaluation of pleural effusions. In recent years, the recognition that analysis of ultrasound artefacts arising from the pleura can provide valuable information about underlying lung pathology has led to wider application of lung ultrasound.[3] Compared with chest radiography and computed tomography (CT), ultrasound is rapid, inexpensive and safe from ionising radiation. Almost all lung parenchymal pathology abuts the pleura and can thus be detected by ultrasound. Diagnostic accuracy of ultrasound compares favourably with CT, and significantly exceeds clinical examination and plain radiography.

EQUIPMENT

Several transducers can be used for chest ultrasound. The standard transthoracic echocardiography, phased array, low-frequency (3–5 MHz) transducer provides good depth penetration and sufficient resolution for most chest ultrasound applications. This transducer is ideally suited for evaluating pulmonary oedema and pleural effusions[5,6] and can therefore be used to complement echocardiographic assessment of cardiac function. A microconvex 5–8 MHz curved array transducer provides better artefact visualisation than lower-frequency transducers, but depth penetration may be insufficient for large patients. The microconvex design facilitates placement of the transducer between the ribs of thin patients.[3] A high-frequency linear array transducer (6–13 MHz) allows detailed pleural line analysis, and is optimal for pneumothorax detection (e.g. after venous cannulation) but has limited other applicability.

Imaging in 2D is adequate for most examinations. M-mode is useful for lung sliding analysis (see below). Doppler imaging is not required.[3]

EXAMINATION TECHNIQUE

Mechanically ventilated patients can usually be satisfactorily examined in the supine or semirecumbent position. Imaging of the posterior lungs is achieved by scanning along the posterior axillary line with the arm lifted out of the way over the anterior chest. A thorough examination of the lungs involves scanning bilaterally over four quadrants of the anterior chest wall (upper and lower zones laterally and medially), the upper and

lower lateral chest wall (bounded by the anterior and posterior axillary lines), and upper, middle and lower zones of the posterior chest wall.[3,7] For a complete study each intercostal space, along multiple vertical lines, should be imaged.[5,6,8] The findings for each space can then be documented in tabulated form. Only the dorsal lung segments behind the scapulae cannot be examined by ultrasound.

Fluid-filled chest pathology (e.g. pleural effusions, atelectasis) is gravity-dependent and thus lies inferiorly. In contrast, aerated pathology (i.e. pneumothorax) is non-dependent, and lies superiorly. Detection of specific pathology should thus be directed accordingly, noting that in the supine patient the least dependent region is the basal anterior chest, which is where a small pneumothorax will collect.[7]

The examination sequence should commence with scanning of the lower lateral chest. Here identification of the diaphragm provides a useful landmark for further imaging. Subdiaphragmatic structures (liver, spleen and kidneys) may be identified to confirm the location of the diaphragm. Right-sided subdiaphragmatic structures are usually easier to visualise than left-sided structures. Diaphragmatic movement with tidal ventilation should be identified. The scanning depth should initially be set to 15–20 cm to evaluate basal lung pathology. The scanning depth can then be reduced to 10 cm (and use of a higher-frequency transducer considered) to facilitate artefact analysis and complete the examination over the whole chest wall.

For each region of interest the transducer should be placed between the rib spaces and aligned with the longitudinal axis of the patient. The orientation marker on the transducer should face cephalad. By convention the orientation marker is displayed on the upper left of the screen with abdominal ultrasound and displayed on the upper right of the screen with echocardiography. Choice of transducer and type of examination selected from the display menu will determine the default marker location on the screen.

IMAGE INTERPRETATION

For every region examined, image interpretation involves each of the following steps:

- identification of the pleural line between the ribs
- artefact analysis
- lung sliding analysis
- evaluation for pathology that can be directly visualised (e.g. pleural effusion, consolidation).

EXTRAPLEURAL LANDMARKS

In 2D mode, with the transducer aligned with the longitudinal axis of the patient, the ribs above and below the pleural space cast a dark shadow that extends down to the full depth of the image on the screen. Between the ribs, the pleural line can be identified as a bright

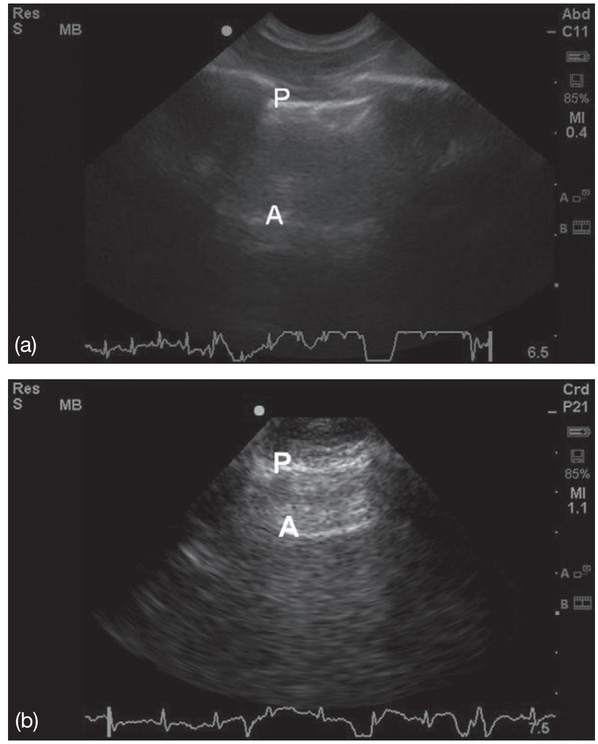

Figure 40.1 A lines demonstrated with a 5–8 MHz microconvex curved array transducer (a) and 1–5 MHz phased array transducer (b). Note the horizontal bright (hyperechoic) pleural line (P) and A line (A) flanked on each side by dark rib shadows.

(hyperechoic) horizontal line located 0.5 cm deep to the outer surface of the ribs (**Fig. 40.1**). The pleural line is the reference line for artefact analysis and lung sliding analysis.

ARTEFACT ANALYSIS

Ultrasound waves cannot be transmitted through aerated tissue. Normal lung parenchyma is thus not visible beyond the visceral pleura. The pleural line is formed by the reflection of ultrasound waves at the interface between the pleura and lung parenchyma (Fig. 40.1). All artefacts used for analysis of lung pathology (except E lines) arise from the pleural line.

- *A-line artefacts* (Fig. 40.1): these are bright horizontal repetitions of the pleural line due to reverberation artefacts, and are a normal finding.[3,9] The vertical distance between two adjacent A lines is the same as the distance between the skin and the pleural line. Usually only one or two A lines are visible depending on image gain and depth settings. A lines are so-called because they are reminiscent of the cross bar of the capital letter A framed by the diagonal shadows cast by the ribs.

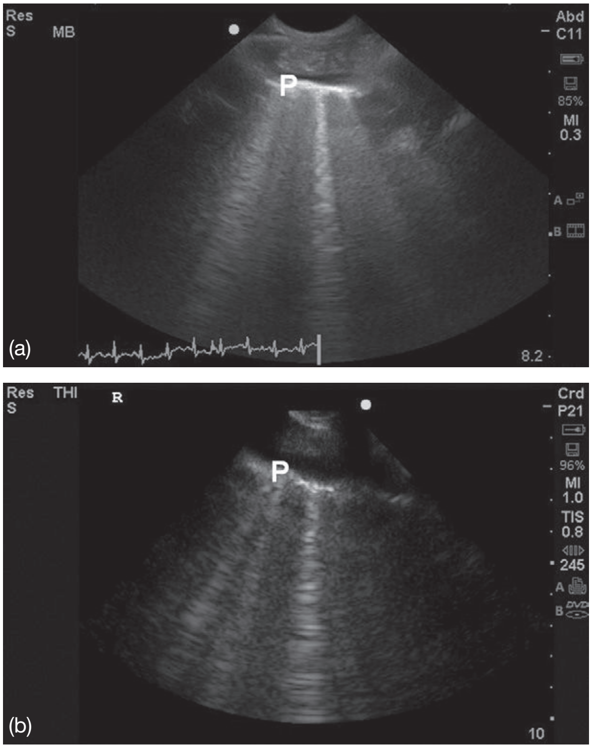

Figure 40.2 B lines demonstrated with 5–8 MHz microconvex curved array transducer (a) and 1–5 MHz phased array transducer (b). Note vertical bright (hyperechoic) lines originating at the pleural line (P) and extending to the bottom of the screen.

- *B-line artefacts* (**Fig. 40.2**): these were previously known as *comet-tail artefacts*[9] or *ultrasound lung comets*,[5] and are defined as discrete vertical bright lines originating at the pleural line and fanning out to the bottom of the screen without fading.[10] B lines arise from reverberation artefacts generated at the interface of fluid-filled or fibrosed interlobular septa abutting the visceral pleura.[9, 11] The presence of multiple B lines, termed '*B pattern*', erases the A-line artefact. With greater loss of aeration the B lines become more closely spaced, or confluent (*white-out*) (**Fig. 40.3**). B lines are equivalent to Kerley B lines seen on the chest radiograph although they may be present before radiographic changes are visible. Isolated B lines or short, ill-defined vertical artefacts are of uncertain significance.
- *E-line artefacts* (**Fig. 40.4**): these have a very similar appearance to B lines, but arise superficial to the pleural line.[3,7] They occur with subcutaneous emphysema where pockets of air create an air–tissue interface that generates reverberation artefacts. It is important to distinguish B lines from E lines by clearly identifying the origin of vertical artefacts in relation to the pleural line; although subcutaneous emphysema is usually easy to detect clinically.

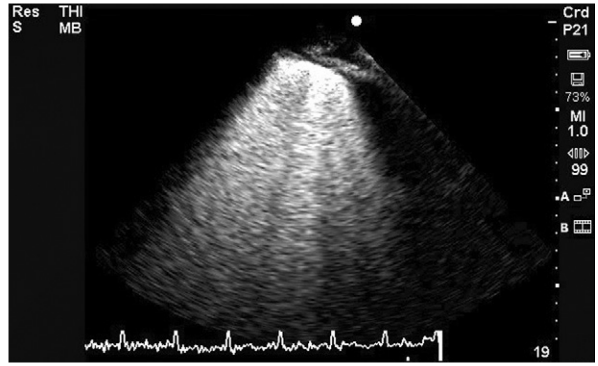

Figure 40.3 Confluent B lines creating a 'white out' appearance, demonstrated with a 1–5 MHz phased array transducer.

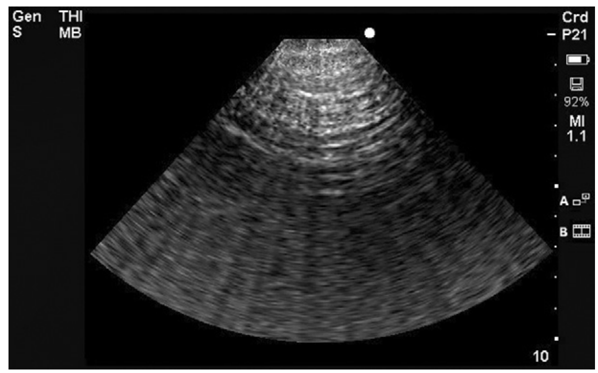

Figure 40.4 E lines demonstrated with a 1–5 MHz phased array transducer. Note the vertical bright (hyperechoic) lines originate above the pleural line, which is poorly defined.

LUNG SLIDING ANALYSIS

With tidal inflation of the normal lung, the visceral pleura slides against the parietal pleura. On ultrasound this is seen as movement below the pleural line. The movement is best appreciated using M-mode imaging, which shows an image reminiscent of the seashore: above the pleural line there are a series of horizontal lines created by extrapleural tissue static in time (the sea), and below the pleural line there is a grainy appearance due to reflection from moving visceral pleura (the beach) (**Fig. 40.5**).[3,7] The transducer must be held completely still on the chest wall. Diagnostic accuracy is improved if a higher-frequency transducer is used. Lung sliding is absent if the visceral pleura cannot be visualised because of air in the pleural space (pneumothorax) (**Fig. 40.6**), or if lung movement is abolished (e.g. pleural fibrosis, dense consolidation, atelectasis or apnoea). Lung sliding may appear absent in patients with chronic obstructive pulmonary disease, or at the apices with small volume tidal ventilation. The *lung pulse sign* (see section on atelectasis below) can be present only when lung sliding is absent (**Fig. 40.7**).[12]

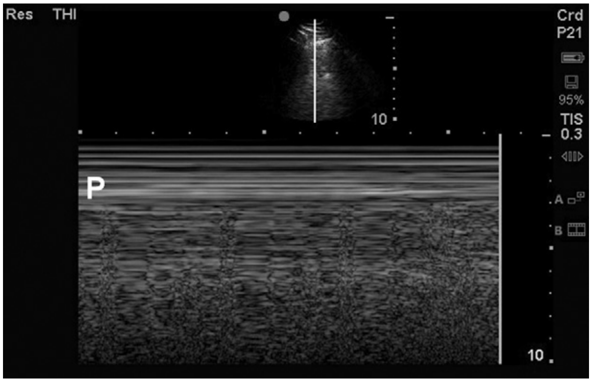

Figure 40.5 Lung sliding (sea shore sign) demonstrated with a 1–5 MHz phased array transducer in M-mode. Note the smooth horizontal lines above the pleural line (P) (extrapleural tissues static over time), and the 'sandy' appearance below the pleural line (due to artefact from visceral pleural sliding with tidal ventilation).

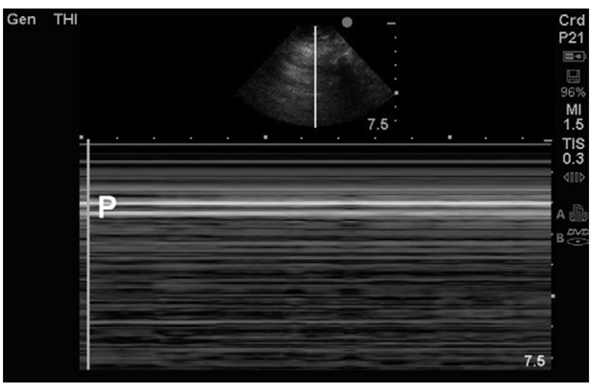

Figure 40.6 Absent lung sliding demonstrated with a 1–5 MHz phased array transducer in M-mode. Note the smooth horizontal lines above and below the bright (hyperechoic) pleural line (P).

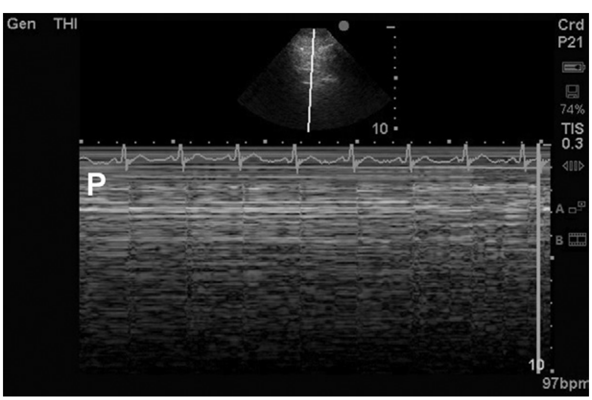

Figure 40.7 Lung pulse sign demonstrated with a 1–5 MHz phased array transducer in M-mode. Note the vertical lines below the pleural line (P) due to transmitted cardiac pulsations.

DIRECTLY VISUALISED PATHOLOGY

Ultrasound waves are able to penetrate non-aerated tissues. Thus pleural fluid, and non-aerated lung pathology (such as consolidation or complete atelectasis), can be readily visualised.

SPECIFIC PATHOLOGIES

The diagnostic accuracy of ultrasound is comparable to CT and superior to plain radiography for all the pathologies discussed below. Ultrasound is also sensitive to rapid changes in severity of disease and can thus be used to monitor disease progression and make timely clinical decisions.[13–15]

The ultrasound appearance of normal lung is characterised by the presence of A lines and lung sliding. About a quarter of normal individuals have one or two B lines at the lung bases[4,5,9] but other artefacts should be absent.

Pleural effusion

Ultrasound enables the detection of small pleural effusions (<50 mL) not visible on chest radiography. Ultrasound can also provides information about the nature of an effusion; septated pleural collections are better characterised with ultrasound than with CT.

Examination for pleural effusion commences with identification of the diaphragm on scanning over the lower lateral chest. The diaphragm appears as a smooth bright (hyperechoic) line overlying the abdominal contents (usually liver or spleen, with the kidneys deep and caudal to these). Pleural fluid manifests as a relatively homogeneous dark (hypoechoic) area between the diaphragm and parietal pleura (**Fig. 40.8**). As pleural fluid acts as an acoustic window, the lung surface (visceral

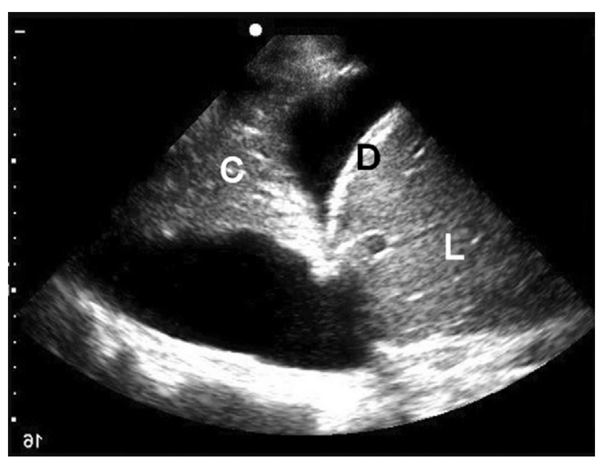

Figure 40.8 Liver (L), diaphragm (D), pleural effusion and collapsed/consolidated lung (C) demonstrated with a 1–5 MHz phased array transducer aligned with the longitudinal axis of the patient in the basal right mid-axillary line.

pleura) can be seen as a regular deep border to the effusion. Aerated lung will show a bright pleural line; often with B lines adjacent to the effusion. Normal lung will tend to float above an effusion, whereas collapsed or consolidated lung will float within a moderate or large effusion (Fig. 40.8). A small pleural effusion confined to the costophrenic angle may be difficult to detect. However, its presence can be inferred if the dome of the diaphragm, which is normally obscured by aerated lung, can be seen. Large effusions allow direct visualisation of mediastinal structures (e.g. aorta and great vessels) if sufficient depth is imaged.

Pleural effusion quantification Various techniques have been described to estimate the volume of pleural fluid.

Measurements are made scanning in the basal intercostal spaces of the posterior axillary line with the transducer aligned in a transverse plane. In supine mechanically ventilated patients, a posterior pleural separation >5 cm strongly predicts a drainage volume of >500 mL.[16] In semirecumbent (15º) mechanically ventilated patients the maximum pleural separation (in mm) multiplied by 20 gives an estimate of drainage volume (in mL).[17] Measurements can be made at either end-expiration or end-inspiration, but are not very reliable at estimating volumes of small or very large effusions. A multiplane method, is obtained by multiplying the longitudinal extent of the effusion by the cross-sectional area at mid length, increases measurement accuracy.[18] However, a precise volume measurement is rarely necessary for clinical decision making.

Nature of pleural effusion Ultrasound characteristics may indirectly suggest the nature of an effusion and can be used to guide the decision whether to perform thoracocentesis. On ultrasound the appearance of an effusion can be categorised as simple, with a uniformly anechoic (black) appearance; or complex, with echogenic material (bright dots), or septa visible within the effusion. Complex effusions can be classified as: complex non-septated with echogenic foci, complex septated, or homogeneously echogenic.[19]

Transudates typically appear anechoic (Fig. 40.8). In addition the low viscosity of a transudate allows substantial movement of lung tissue with tidal ventilation. This is best appreciated as a sinusoidal pattern of the lung surface line with M-mode during tidal ventilation.[3] The pleural line is usually smooth.

Exudates are usually but not always complex. On M-mode imaging there is minimal sinusoidal movement with tidal ventilation if the exudate is very viscous. The pleural line may appear thickened and irregular from pleural inflammation. A homogeneously echogenic pattern may be almost tissue-like in appearance and should not be mistaken for an area of consolidation (see below). In patients who clinically appear infected, a complex, relatively hyperechoic, septated, or homogeneously echogenic pattern suggests empyema. An anechoic or minimally hyperechoic pattern is unlikely to represent empyema.[19] Haemothoraces appear complex with septa and areas of differing echogenicity, depending on the age of the blood.

Thoracocentesis Ultrasound guidance of thoracocentesis decreases complications and improves fluid collection rates.[4] It allows identification of the optimal site for drainage, and measurement of the depth of the pleural space. Potential hazards such as the diaphragm or pleural adherences can be avoided, and the risk of intrafissural or intraparenchymal tube placement reduced. The decision to perform thoracocentesis is based on size, suspected nature of the effusion and clinical circumstances.

Alveolar consolidation

Consolidated lung (except bronchi) is not aerated and can therefore be directly visualised where it abuts the pleura, or where there is a pleural effusion between the chest wall and consolidated lung (**Fig. 40.9**).[12,20] Artefacts that arise from the pleural line are absent, although B lines may be seen at the edges of consolidated areas. Consolidation is rarely confined just to deeper lung tissue, almost always extending to involve peripheral lung tissue adjacent to pleura. The full extent of consolidation can thus usually be defined. In mechanically ventilated patients consolidation preferentially affects the basal posterior lung segments. By contrast, with community-acquired pneumonia consolidation may affect any lung region.

The echo-texture of consolidation resembles that of liver (hepatisation), although usually coarser in appearance (Fig. 40.9). When examining the right basal chest, care should be taken to distinguish between

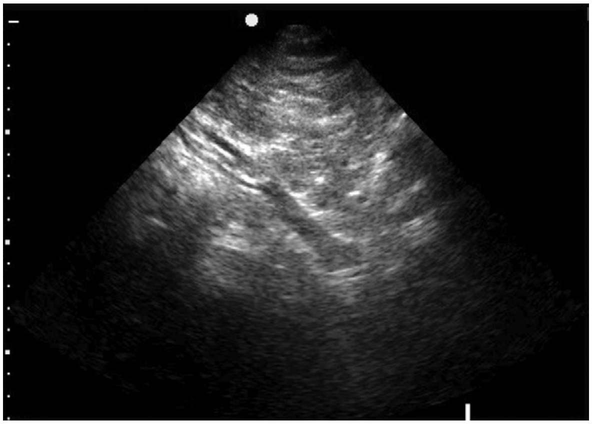

Figure 40.9 Consolidated lung demonstrated with a 1–5 MHz phased array transducer aligned with the longitudinal axis of the patient in the mid left mid-axillary line. Note the dark (hypoechoic) diagonal region representing the oblique fissure, and the bright (hyperechoic) punctiform air bronchograms.

Table 40.1 Lung ultrasound reaeration score[13,14]*

LUNG PATHOLOGY	DEGREE OF AERATION	ULTRASOUND FINDINGS
Normal lung	More aeration	A lines
Interstitial infiltrate	⇕	B lines
Alveolar–interstitial infiltrate		White out (confluent B lines)
Alveolar consolidation	Less aeration	Consolidation

*Loss of aeration may be due to oedema, inflammation or fibrosis.

consolidated lung and liver parenchyma by clearly identifying the diaphragm (Fig. 40.8). The borders of the consolidated area may be irregular at the junction with normal lung tissue, but will be regular if the full thickness of lung is affected.

Within consolidated lung, air bronchograms appear as bright (hyperechoic) punctiform or linear artefacts (Fig. 40.9). The air bronchogram artefact moves with respiration (dynamic air bronchogram), outwards (towards the transducer) with inspiration and inwards (away from the transducer) with expiration.[21] The dynamic air bronchogram distinguishes consolidation from resorptive atelectasis.[21]

Atelectasis

Resorptive atelectasis commonly affects the dependent lung regions of mechanically ventilated patients. On ultrasound the affected lung appears consolidated, but air bronchograms are static with respiration.[21]

Complete lobar collapse may occur with bronchial intubation or mucus plugging. This can be detected immediately on ultrasound by absence of lung sliding and the lung pulse sign.[12] These signs are best appreciated using M-mode imaging with a high-frequency transducer. The lung pulse sign consists of vibrations in the M-mode trace (below the pleural line) due to transmitted cardiac pulsations (see Fig. 40.7). Over time, progressive absorption of gas leads to the development of consolidated lung (resorptive atelectasis).

Alveolar–interstitial syndrome

Alveolar–interstitial syndrome encompasses disease processes with which there is predominant interstitial involvement, and partial loss of lung aeration. In the acute setting this is most often due to hydrostatic or capillary leak pulmonary oedema. Less common causes include interstitial fibrosis (interstitial pneumonia) and opportunistic infection (in immunocompromised patients). Ultrasound has a high diagnostic accuracy for alveolar–interstitial syndrome.[9]

On ultrasound the hallmark of alveolar–interstitial syndrome is the presence of multiple (at least three) B lines largely independent of patient positioning.[5,9] The ultrasound pattern of B lines corresponds to the degree of lung aeration.[14] In mild disease, where thickening is confined to interlobular septa, the B lines are characteristically 7 mm apart (measured at the pleural line) (see Fig. 40.2). With progressive pulmonary oedema and increasing alveolar flooding, or with fine fibrosis, B lines are more closely spaced (approximately 3 mm apart). In severe cases B lines become confluent creating a 'white-out' pattern (see Fig. 40.3); this pattern is equivalent to ground-glass opacification on CT.[4,9,22] Complete alveolar flooding is indistinguishable from primary alveolar consolidation.[14,22] With respiration the B lines move to-and-fro across the screen with lung sliding.

In acute alveolar–interstitial syndrome a number of ultrasound findings can be used to distinguish acute respiratory distress syndrome (ARDS) from cardiogenic pulmonary oedema.[22] ARDS is characterised by a non-uniform distribution of B lines, with areas of normal lung and areas of confluent B lines or white-out. Areas of consolidation are often present, particularly in the posterobasal regions. Lung sliding is reduced, or absent, in densely affected regions and the pleural line appears irregular, thickened and coarse when examined with a high-frequency transducer. In contrast, cardiogenic pulmonary oedema shows a homogeneous distribution of B lines. Consolidation is infrequent and pleural line abnormalities are absent. Pleural effusions are common.

With cardiogenic pulmonary oedema a *lung comet score* can be used to provide a semiquantitative measure of extravascular lung water. The score is obtained by adding together the number of B lines seen from each intercostal space examined over the anterior and lateral chest.[5,6,8] The number of B lines has been shown to correlate with functional class, and severity of systolic and diastolic left ventricular dysfunction on cardiac echocardiography.[6] Reduction in lung comet score occurs with resolution of interstitial oedema.[15] An absence of B lines is consistent with a low pulmonary artery occlusion pressure.[23,24] During fluid resuscitation, the new appearance of B lines heralds the development of interstitial oedema before radiographic changes are visible.

In ALI/ARDS a lung ultrasound *reaeration score* based on the severity of interstitial changes (**Table 40.1**) provides a semiquantitative measure of positive end-expiratory pressure induced lung recruitment.[14] The lung ultrasound reaeration score has also been used to

evaluate resolution of ventilator-associated pneumonia with antibiotics.[13]

Pneumothorax

The diagnosis of pneumothorax by ultrasound requires more expertise than other aspects of chest ultrasound,[4] due to the reliance on artefact analysis and low incidence of pneumothorax. However, in experienced hands the diagnostic accuracy of ultrasound for occult pneumothorax, defined as pneumothorax visible on CT but not plain radiograph, matches that of CT.[7]

As free pneumothorax is non-dependent, signs of pneumothorax should be sought anteroapically in the semirecumbent patient or anterobasally in the supine patient. Where there is a pneumothorax the parietal and visceral pleura are separated by air through which ultrasound waves cannot penetrate. Thus any lung pathology, or artefacts abutting or arising at the visceral pleura, cannot be visualised; lung sliding, B lines and the lung pulse sign must be absent. However, the A-line sign is present, generated at the tissue/air interface of the parietal pleura. The combination of A lines, absent B lines, absent lung sliding and absent lung pulse sign is 100% sensitive, but not specific for pneumothorax. Detection of the edge of the pneumothorax, termed the *lung point sign*, confirms the diagnosis of pneumothorax and allows a rough assessment of its size.[7] With the transducer held perfectly still, using 2D mode, the lung is seen to slide in and out of view with tidal ventilation. This can also be appreciated using M-mode imaging, which shows alternating lung sliding and absent lung sliding. The lung point sign will be visualised anteriorly with an occult or small pneumothorax and more laterally with a moderate-sized pneumothorax.[7] The lung point sign will be absent with a large pneumothorax, where lung sliding is absent over the entire chest.[7] In mechanically ventilated patients, care should be taken to avoid mistaking a temporary cessation of lung sliding, due to a pause in ventilation, for true lung sliding; the lung pulse sign should be present with pauses in ventilation.

A false-positive diagnosis of pneumothorax is more likely in patients with chronic obstructive pulmonary disease. If clinical uncertainty remains then chest CT may be indicated. During cardiopulmonary resuscitation the exclusion of pneumothorax may be particularly difficult, because lung sliding will be absent unless there is effective ventilation, and the lung pulse sign will be absent during apnoeic periods because of the lack of cardiac contractility.

Subcutaneous emphysema is characterised by an air–liquid interface superficial to the pleural line. This creates E-line artefacts, which are similar in appearance to B lines but arise superficially to the pleural line (see Fig. 40.4). The presence of subcutaneous emphysema is suggestive of pneumothorax. Unfortunately, the presence of E lines precludes further ultrasound analysis for signs of pneumothorax or other lung pathology. In these circumstances other imaging techniques may be required depending on the clinical circumstances.

DIAPHRAGMATIC DYSFUNCTION

Ultrasound promises to be a simple and safe alternative to fluoroscopy or phrenic nerve conduction studies for the diagnosis of diaphragmatic dysfunction. Ultrasound techniques are based on the measurement of either the extent of diaphragmatic excursion with respiration viewed from the anterior or lateral upper abdomen, or changes in diaphragm thickness at the zone of apposition between the diaphragm and the basal, lateral chest wall.[25–27] Measurements can be made using 2D or M-mode.[25–27]

DIAGNOSTIC ALGORITHMS

A number of algorithms exist that incorporate chest ultrasound in the diagnostic assessment of patients with undifferentiated respiratory failure, shock, trauma (E-FAST) or cardiac arrest.

The Bedside Lung Ultrasound in Emergency (BLUE) protocol combines lung ultrasound with deep-vein ultrasound to facilitate a diagnosis in patients with acute respiratory failure.[28] A diagnosis of pulmonary embolus may be inferred from the combination of clear lungs and deep vein thrombosis on ultrasound, as direct diagnosis of pulmonary embolism with lung ultrasound is problematic.[29] Echocardiography can be added for a complete assessment of respiratory failure. For undifferentiated hypotension or shock, abdominal ultrasound is also added to detect free peritoneal fluid and abdominal aortic aneurysm.[30]

ABDOMINAL ULTRASOUND

A complete ultrasound examination of the abdomen requires radiological expertise. However, detection of haemoperitoneum (and haemopericardium) with Focused Assessment with Sonography in Trauma (FAST) is well established in emergency medicine,[31–33] and the same examination sequence can be readily applied to the intensive care patient to detect intraperitoneal fluid of any cause. Examples include detection of haemoperitoneum after abdominal surgery, or ascites in patients with chronic liver disease and portal hypertension. Once detected, if the ascites requires paracentesis the optimal location for needle puncture can be determined by scanning more widely over the abdomen.

Low-frequency curved or phased array transducers are suitable for the FAST examination. The examination sequence consists of four standard views:[31,32]

- *Right upper quadrant:* with the transducer in the mid axillary line, aligned with the longitudinal axis of the patient (orientation marker cephalad). Three potential spaces where fluid may collect are examined in turn by moving the transducer cephalad and caudad:

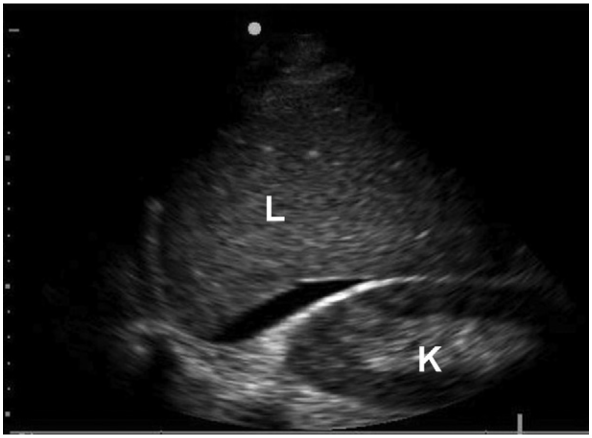

Figure 40.10 Right upper quadrant FAST scan (1–5 MHz phased array transducer) demonstrating free intraperitoneal fluid in the hepatorenal recess (Morison's pouch). Liver (L), kidney (K).

the subdiaphragmatic space, hepatorenal recess (Morison's pouch) and around the inferior pole of the kidney (**Fig. 40.10**). In the supine patient, the hepatorenal recess is the most dependent and sensitive site for detection of peritoneal fluid accumulation.

- *Left upper quadrant:* with the transducer aligned longitudinally along the posterior axillary line. The subdiaphragmatic, splenorenal and inferior renal pole regions are examined. Fluid is more likely to be detected subdiaphragmatically than in the splenorenal recess, because the phrenocolic ligament closely apposes the spleen and kidney.[30]
- *Pelvis:* with the transducer just cephalad to the symphysis pubis and directed caudally. Images should be obtained in both longitudinal and transverse planes. The pelvis view is difficult to obtain if the bladder is decompressed (urinary catheter in situ), because the filled bladder is used as an 'acoustic window' to the pelvic peritoneal spaces.
- *Subcostal cardiac view:* to detect pericardial effusion.

The Extended-FAST (E-FAST) examination adds focused lung ultrasound for the detection of traumatic haemothorax and pneumothorax.[32] The basal anterior chest is examined bilaterally (supine patient) for signs of pneumothorax, and the basal posterolateral chest is examined for pleural fluid (haemothorax).

ULTRASOUND-GUIDED VASCULAR CANNULATION

Central venous cannulation is an essential component of intensive care practice. With the traditional 'landmark technique' location of the vein for cannulation is based on identification of skin surface anatomical landmarks and palpation, and is reliant on normal anatomy and venous patency. Complications include failure to cannulate the vein, pneumothorax, arterial puncture, haematoma, haemothorax and nerve injury. Risk of complication depends on operator experience, urgency and patient comorbidities; with reported rates of 5–20%.[34] Inclusion of ultrasound with the procedure improves first-pass success, leads to lower complication rates and is advocated by patient safety practice recommendations.[34–38] Ultrasound can also be used to aid arterial cannulation.[39]

ULTRASOUND TECHNIQUE

For the ultrasound novice, learning the necessary skills to image the central veins requires only a short period of supervised training, although developing good hand–eye coordination for real-time imaging during cannulation may take longer.

A high-frequency (7–11 MHz) linear transducer provides optimal image resolution suitable for vascular structures close to the skin surface. The vertical imaging depth should be set to ensure complete visualisation of the vein to be cannulated and significant structures (e.g. artery) deep to the vein. To avoid left–right confusion, the orientation marker on the screen should match the orientation of the transducer on the patient.

Ultrasound can be used in an indirect or direct way to assist cannulation. With the indirect (static) approach, imaging is used only prior to skin preparation to confirm location and patency of the vein. This avoids the need for a sterile transducer cover, but doesn't account for distortion of anatomy during needle puncture and may increase the risk of needle damage to the posterior vessel wall.[38] This technique is best suited to cannulation of large superficially located veins. The direct (dynamic) approach involves real-time ultrasound guidance of needle insertion. The vein can be imaged in a transverse or longitudinal plane. Transverse imaging gives a better view of the anatomical relationships of the vein to surrounding structures (**Fig. 40.11**). However, the full depth of the needle may be difficult to visualise (**Fig. 40.12**).[36–41] Longitudinal imaging provides optimal visualisation of the entire length of the needle and its depth of insertion[41,42] but is technically more difficult than cannulation with transverse imaging.[36,38] The direct approach requires sterile gel and transducer cover.

VESSEL IDENTIFICATION

The anatomical position of the artery and vein may vary from the usual pattern, particularly in the neck. Certain characteristics are used to distinguish vein from artery and determine venous patency.[38] Veins are thin-walled, elliptical in cross-section and compressible with light external pressure (see Fig. 40.11). Arteries are thick-walled, circular in cross-section, and more pulsatile (during normal haemodynamic conditions). Veins are usually larger than the adjacent artery; however, the

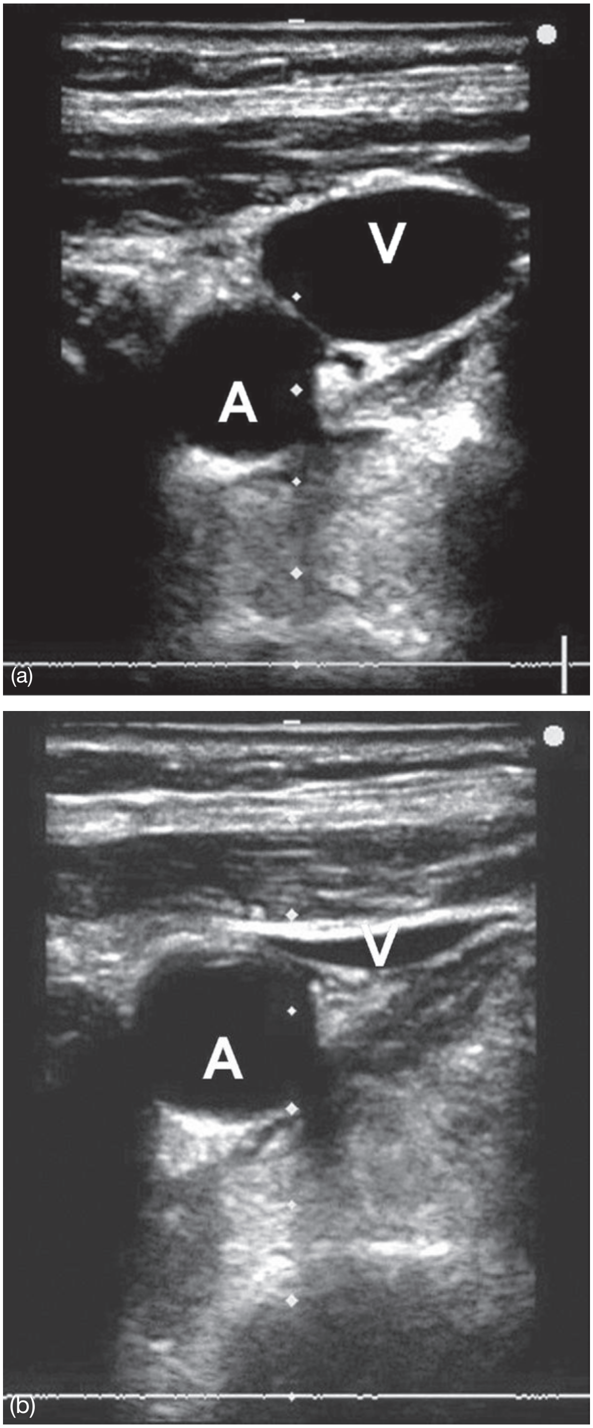

Figure 40.11 Right IJ vein (V) and carotid artery (A) imaged in a transverse (short axis) plane with a 6–13 MHz linear array transducer. The vein has an oval contour without external compression (a), but appears slit-like when light external compression is applied (b). The depth markers down the centre of the image are at half-centimetre intervals.

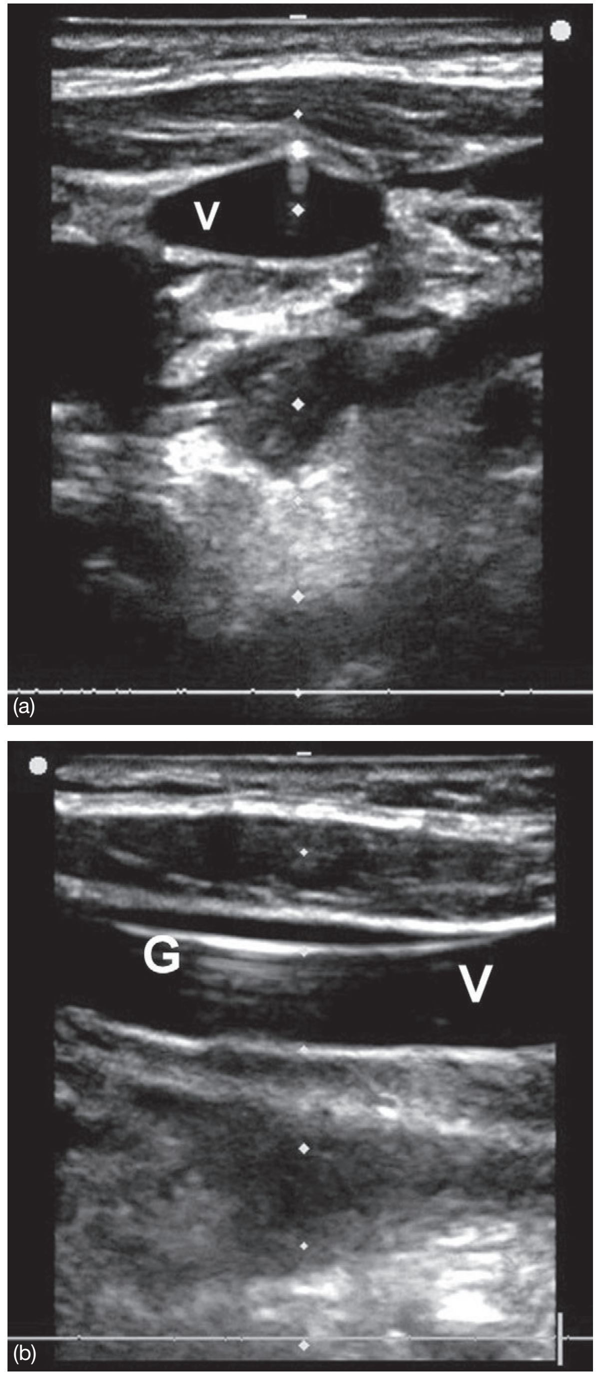

Figure 40.12 Right IJ vein cannulation demonstrated with a 6–13 MHz linear array transducer. In the transverse (short-axis) image (a) the needle is visualised in cross-section as a bright (hyperechoic) dot seen at the top of the vein (V). Note that in this still image it is not possible to determine which part of the needle shaft is being visualised and thus at what depth the needle tip is. The longitudinal (long-axis) image (b) shows the guidewire (G) within the vein (V).

internal jugular vein may appear smaller due to anatomical variation or hypovolaemia, and will appear slit-like in the hypovolaemic patient who is not in the Trendelenberg position. Colour flow Doppler demonstrates pulsatile arterial blood flow during systole. Venous blood flow is visible on colour flow Doppler during both systole and diastole if a low-velocity (Nyquist) scale is used.

Thrombus appears as an irregular filling defect that is often quite mobile. Thrombus downstream from the site where the vein is being scanned may not be visible, but its presence can be suspected if the vein is incompressible with light pressure. Absence of colour flow Doppler across part of the venous lumen may help to identify thrombus.

INTERNAL JUGULAR VEIN CANNULATION

Cannulation of the internal jugular (IJ) vein is ideally suited to ultrasound guidance because of the ease with which good images can be obtained, and the significant incidence of anatomical variants. The IJ vein is classically described as being located lateral to the carotid artery as it courses behind the sternocleidomastoid muscle between the anterior and posterior triangles of the neck. However, in a small proportion of patients the IJ vein runs medial to the carotid artery and in the majority of patients the vein overlies the artery to some extent.[36,38] The degree of overlap is increased by excessive head rotation away from the neutral position, and is more likely to occur with older age and obesity. In two-thirds of patients the right IJ is larger than the left IJ.[43] A quarter of patients have one IJ vein less than 0.4 cm^2 in cross-sectional area.[43] As anatomical variation is not predictable a priori from skin surface features, ultrasound should be used for IJ vein cannulation (**Box 40.1**).[34,36,38]

Box 40.1 A suggested approach to direct ultrasound guidance of IJ vein cannulation using the Seldinger method

1. Obtain informed consent for procedure
2. Place patient in Trendelenberg position with head slightly rotated away from the side to be cannulated
3. Image IJ vein to determine suitability for cannulation; presence of unsuitable anatomy or thrombus should prompt cannulation of an alternative site
4. Ensure appropriate ultrasound depth, marker position and gain settings
5. Prepare and drape sterile field
6. With the help of an assistant, apply sterile sheath over transducer with coupling gel inside sheath and separate sterile coupling gel outside sheath
7. Scan along the vein to determine the optimal site for venous puncture, i.e. easy to access with needle, large cross-sectional area and minimum overlap with the carotid artery. The degree of head rotation may need to be adjusted to minimise vessel overlap
8. For right-handed cannulation hold the transducer with the left hand
9. If imaging in a transverse (short-axis) plane, advance the needle incrementally and then adjust the transducer position each time to ensure visualisation of the needle tip (Fig. 40.12). With longitudinal (long-axis) imaging puncture the skin with the needle directly underneath one end of the transducer; adjust the needle direction (not the transducer position) to ensure that it remains visible on the screen as the needle advances. With either method, needle damage to the posterior wall of the vein may be less with a bevel-downward rather than bevel-upward approach[44]
10. Once venous blood is aspirated, place the transducer on the drapes and hold the needle with the left hand whilst removing the syringe from the needle with the right hand
11. Insert the guidewire into the needle with the right hand
12. Remove the needle over the guidewire and then scan over the vein to confirm satisfactory guidewire placement (Fig. 40.12)
13. Dilate and cannulate the vein over the guidewire to complete the procedure

SUBCLAVIAN VEIN CANNULATION

More consistent surface landmarks and less anatomical variation make the landmark technique for subclavian (SC) vein cannulation very reliable. However, if unsuccessful after two attempts, the risk of complications (pneumothorax, subclavian artery puncture) increases significantly with further attempts.[38] Ultrasound may be used to guide SC vein cannulation, but the clavicle often obscures a clear image of the vein. A microconvex transducer (which is easier to place under the clavicle than a linear transducer) sometimes improves visualisation of the vein. Alternatively cannulation can be attempted from a more lateral, axillary vein, approach, where the clavicle does not obscure imaging of the vein. This latter technique requires a steeper angle of needle entry with potential risk of pneumothorax, and should be attempted only under direct ultrasound guidance.[38] The axillary vein approach has been reported to be superior to the standard landmark technique in both novice and experienced operators.[45,46] Routine use of ultrasound for SC cannulation is not supported by current literature, but is recommended in high-risk patients to identify SC vein location and patency, or to guide an axillary vein approach.[38] Following the procedure, ultrasound can also be used to examine the lung for evidence of pneumothorax.

FEMORAL VEIN CANNULATION

The femoral vein can be reliably identified from surface landmarks and palpation of the femoral artery. The femoral vein is usually medial to the femoral artery,

but significant vessel overlap may occur, particularly in children.[47] Ultrasound is recommended to identify vessel overlap and patency.[38]

OPTIC NERVE ULTRASOUND

Simple 2D ultrasound measurement of the diameter of the nerve sheath surrounding the optic nerve provides a rapid, non-invasive method of detecting elevated intracranial pressure (ICP). In patients presenting to hospital with suspected traumatic brain injury, ultrasound-measured optic nerve sheath diameter (ONSD) identifies patients with elevated ICP who warrant further neuroimaging.[48,49] Furthermore, with traumatic brain injury changes in ONSD correlate with changes in invasively measured ICP.[50, 51] However, invasive monitoring remains the gold standard for ICP measurement where this is not contraindicated by a risk of infection or haemorrhage. Validation of ultrasound ONSD is limited in other clinical settings, for example metabolic disorders (e.g. acute hepatic failure, diabetic ketoacidosis), or cerebrovascular disease (stroke syndromes).

The optic nerve sheath is a continuation of the meningeal layer surrounding the brain. Increases in ICP are transmitted by the cerebrospinal fluid through the perineural subarachnoid space to cause oedema and swelling of the optic nerve sheath that can be detected with ultrasound. The sheath is most porous and thus becomes most swollen 3 mm deep to the optic disk.

A high-frequency (10–15 MHz) linear transducer is used with the image depth set to 3–4 cm. A thick layer of acoustic gel is applied over the closed upper eyelids, with the patient lying supine or 20º head up. The transducer is then lightly placed over the upper, lateral eyelid, with the examiner's hand resting on the patient's forehead and the transducer held like a pencil. Care must be taken to ensure that no pressure is applied to the globe with the transducer. To reduce the risk of harmful effects (cavitation) of ultrasound acoustic output the mechanical index (MI) should be set to less than 0.23. The possibility of thermal damage is limited by scanning for less than 5 minutes.

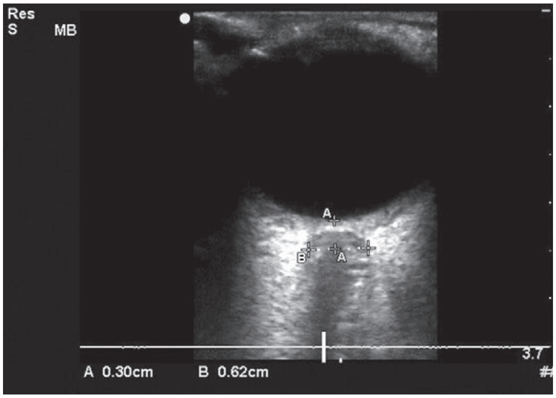

Figure 40.13 Globe and optic nerve demonstrated with a 6–13 MHz linear array transducer. Measurement of the optic nerve sheath diameter (vertical calliper) is demonstrated 3 mm deep (horizontal calliper) to the optic nerve head.

The optic nerve is seen as a hypoechogenic column beyond the globe and optic disk, surrounded bilaterally by the hyperechogenic optic nerve sheath (**Fig. 40.13**). With the optic nerve aligned directly opposite the transducer, the optic nerve sheath diameter is measured perpendicular to the vertical axis of the imaging plane, at a depth of 3 mm from the optic disk (see Fig. 40.11). At this depth detection of significant swelling is maximised, and distortion of ONSD measurement by artefactual shadowing is minimised. Several measurements should be taken in both longitudinal and transverse imaging planes, and the results averaged for each eye. Measured in this fashion normal values for ONSD are <5 mm. Values greater than 5.7–6.0 mm predict an elevated ICP (>20 cmH_2O) with good sensitivity and specificity.[49] Inaccuracies can arise if the transducer is orientated in a strictly axial imaging plane, with the optic nerve scanned along the visual axis. This results in a fusiform appearance of the optic nerve, and potentially unreliable ONSD measurements.[52] Imaging directly through the cornea and lens may also generate artefacts and reduce measurement reliability.

Extracorporeal membrane oxygenation (ECMO)

Vincent Pellegrino

41.1 ECMO for respiratory failure

The management of severe lung injury remains a significant problem in critically ill patients. Despite the use of protective mechanical lung ventilation, the mortality of patients with severe acute respiratory distress syndrome (ARDS) remains high and increases with the severity of lung injury.[1,2] Protective lung ventilation in patients with severe ARDS may be limited by progressive hypoxaemia and hypercapnia despite recourse to adjunctive therapies that improve oxygenation, such as inhaled nitric oxide (NO) or prone positioning.

Veno-venous extracorporeal membrane oxygenation (VV ECMO) is an alternative form of lung support that provides non-pulmonary oxygen delivery and carbon dioxide removal, facilitates lung protective ventilation and provides time for lung recovery. Although previously predominately used as a neonatal and paediatric support, it is now increasingly being used in adults.[3]

Current ECMO systems are mobile, can facilitate inter-hospital patient transport even over long distances, can be instituted quickly and provide support over days to months.

DEFINITIONS

ECMO

EXTRACORPOREAL MEMBRANE OXYGENATION (ECMO)

This is a form of extracorporeal support comprising specialised *access cannula* to drain venous blood, an external circuit (*tubing*), a gas exchange device (*oxygenator*) where blood becomes enriched with oxygen (O_2) and has carbon dioxide (CO_2) removed, and a *return cannula* through which circuit blood returns to the patient. A pump drives the circuit blood flow and heat exchange is possible. A *fresh gas flow* is delivered to the oxygenator. ECMO can provide adequate oxygenation and CO_2 clearance in patients with minimal or absent native lung function. ECMO may achieve circuit blood flows up to approximately 7 litres of blood per minute.

MODE

The vessels from which ECMO circuit blood is obtained and returned define the *mode of ECMO*. Veno-venous ECMO (VV ECMO) is the ECMO mode used for respiratory support. Blood is removed from the great veins and returned to the right atrium and the patient's native circulation is powered entirely by the heart. Veno-arterial ECMO (VA ECMO) should not be used to support isolated respiratory failure.

CONFIGURATION

The *configuration of VV ECMO* refers to the manner in which the cannulae interact with the native circulation and is defined by the cannulae insertion sites, the type of cannula used and the tip positions (**Table 41.1.1**). *Access cannulae* drain blood from the venous system under negative pressure and may be either single-stage or multi-stage. Single-stage cannulae drain blood from a short region near the tip only. Multi-stage cannulae drain blood through side holes over a long length of the cannula, in addition to the tip, and allow a greater negative pressure in the circuit. For this reason they can provide higher circuit blood flow. *Return cannulae* deliver blood back to the patient under positive pressure from the ECMO circuit and expel blood only near the cannula tip (single stage). A double-lumen cannulae is available for adult VV ECMO support (Avalon Elite™) that contains both access and return lumens in a single cannula.[4]

$ECCO_2R$

Extracorporeal CO_2 removal ($ECCO_2R$) systems differ from ECMO. They use smaller cannulae, low-blood-flow extracorporeal circuits and oxygenators, and predominately remove CO_2.[5] Circuit blood flow is limited to less than 3 litres per minute and such systems cannot support patients with minimal lung function or severe hypoxaemia but can eliminate virtually all the CO_2 produced. By controlling CO_2, they facilitate protective lung ventilation.[6] Recently, a number of new $ECCO_2R$ systems have become available. Current $ECCO_2R$ systems may be pump-driven veno-venous systems with a membrane oxygenator (PALP™, Maquet or Hemolung RAS)[7,8] or be 'pumpless' and use an arterio-venous mode (iLA Membrane Ventilator® Novalung)[9] or utilise a dialysis membrane in addition to the gas exchange membrane (DECAPsmart®, Hemodec).[10]

Table 41.1.1 Configurations of VV ECMO

CONFIGURATION	INSERTION SITE	CANNULA TIP POSITION	CANNULA TYPE AND SIZE	ADVANTAGES / DISADVANTAGES
Femoro-femoral (fem-fem)	*Access:* Right or left femoral veins *Return:* Right or left femoral veins	*Access:* Hepatic IVC *Return:* Right atrium	*Access:* Multi- or single-stage (21–25F) *Return:* Single-stage (21–23F)	*Advantages:* Rapid to establish, safe, easy to secure and transport *Disadvantages:* Frequent problems with access insufficiency
Femoro/jugular–femoral[42] (high-flow)	*Access:* Femoral vein and right jugular vein *Return:* Femoral vein	*Access:* Hepatic IVC and SVC *Return:* Right atrium	*Access:* Multi- or single-stage (21–25F) and short single-stage cannula (17–19F) *Return:* Single-stage (19–23F)	*Advantages:* Can fully support severe respiratory failure even in large patients *Disadvantages:* Multiple cannulation required
Femoro-jugular (Fem-Jug)	*Access:* Femoral vein *Return:* Right jugular vein	*Access:* Hepatic IVC *Return:* SVC/right atrium	*Access:* Multi-stage (21–25F) *Return:* Short single-stage (19–21F)	*Advantages:* Full support and infrequent access insufficiency *Disadvantages* Longer to insert, difficult to secure and maintain dressing, decannulation risk
Dual-lumen/two-stage (Avalon)	Right jugular vein	*Access:* Hepatic IVC and SVC *Return:* Right atrium	31F	*Advantages:* Single cannulation, allows ambulation *Disadvantages* Difficult to secure and maintain dressings, high circuit pressures

In all cases, ECMO blood flow travels from the vena cavae to the atria (cavo-atrial flow) to minimise recirculation.

GAS EXCHANGE PRINCIPLES IN VV ECMO

OXYGEN DELIVERY

Delivery of oxygen to the circuit blood by the oxygenator is governed by the oxygen-carrying capacity of the blood. Current adult membrane oxygenators can oxygenate up to 7 litres of deoxygenated blood flow per minute. The quantity of oxygen that can be delivered to the patient on VV ECMO depends on the quantity of blood arriving at the oxygenator (circuit blood flow), the preoxygenator O_2 saturation and the haemoglobin. Additional fresh gas flow to the oxygenator cannot increase the oxygen delivery to the circuit blood. *In the presence of a large pulmonary shunt, the patient's arterial oxygen saturation will depend predominately on the proportion of deoxygenated venous return that can be captured by the VV ECMO circuit.* Capturing additional deoxygenated venous blood with VV ECMO will improve the arterial oxygen saturation. The oxygen consumption and haemoglobin will also affect the patient's arterial oxygen saturation in the presence of a large lung shunt.

CARBON DIOXIDE REMOVAL

Removal of CO_2 *by the membrane oxygenator is largely determined by the ratio of fresh gas flow to circuit blood flow in the oxygenator*. For a given circuit blood flow, increasing the fresh gas flow to the oxygenator will increase CO_2 removal. The fresh gas flow rate to the membrane oxygenator is titrated to achieve a desired partial pressure of CO_2 in the arterial blood. Normally, the ratio of fresh gas flow (L/min) to the circuit blood flow (L/min) at commencement of ECMO is approximately 1:1. With lung recovery, fresh gas flow can be gradually reduced while maintaining circuit blood flow. When the lung is capable of safely removing all CO_2 production, fresh gas flow is ceased to the oxygenator and extracorporeal respiration ceases.

RECIRCULATION

Optimal configuration of VV ECMO must ensure adequate separation between the access and return cannulae within the venous system in order to minimise

recirculation of ECMO circuit blood flow.[11] Blood entering the oxygenator with high oxygen content, can accept little additional oxygen owing to the nature of the oxygen content curve. This will greatly reduce the quantity of oxygen delivery the patient can receive from the ECMO circuit and may be a cause of arterial hypoxaemia. Some degree of recirculation is inevitable, particularly at higher pump blood flow rates. Clinically significant recirculation results in a reduced colour difference between pre- and postoxygenator blood (both appear bright red) or an O_2 saturation of over 80% in the preoxygenator blood. In contrast, recirculation does not reduce CO_2 clearance.

HIGH OXYGEN CONSUMPTION

High cardiac output in conjunction with high oxygen consumption due to illness, patient size and fever may result in hypoxaemia, despite optimal VV ECMO configuration, and maximal circuit blood flow ≥7 L/min. This is associated with low preoxygenator oxygen saturation (<60%).

EQUIPMENT

Current generation blood pumps, membrane oxygenators and circuit coatings have improved the safety and reliability of ECMO.[12] This has allowed less-specialised bedside staffing and allowed ECMO care to be integrated into the scope of practice of ICU medical and nursing staff.[12] Major features are given below.

ROTARY PUMPS

Rotary pumps have largely superseded roller pumps and offer many advantages when used in circuits with low resistance to flow. These magnetically coupled pumps generate a rotational force, which drives blood radially within the pump head. A negative pressure is generated in the centre of the pump (inlet) and a positive pressure at the periphery (outlet). The pressure gradient within the pump head drives circuit blood flow, which is proportional to the rotational speed controlled by the operator. The pressure load across the circuit and the circuit resistance determine the actual circuit flow rate. The pressure load across a VV ECMO circuit is negligible as both access and return cannula are sited in the venous system. Pump head thrombosis, which can cause rapid and very severe haemolysis, is extremely rare with current rotary pump heads.

MEMBRANE OXYGENATORS

Membrane oxygenators made from polymethylpentene have markedly improved the safety and reliability of ECMO.[13] Plasma leak across the membrane seen in previous microporous membrane oxygenators has been eliminated. They allow high gas transfer with low resistance to blood flow and can be coated to minimise activation of coagulation. Acute oxygenator failure is now extremely rare.

SURFACE COATINGS

Surface coatings to reduce blood–surface interaction and activation of coagulation and inflammatory systems are present on all current ECMO components. The patient-centred benefits of one coating compared with another have not been established in ECMO.[14,15]

INDICATIONS AND PATIENT SELECTION

VV ECMO is indicated for life-threatening forms of acute respiratory failure where the risks of less-invasive support are considered greater than the risks of ECMO (**Fig. 41.1.1**). It is predominately used to provide support and allow time for recovery of the underlying condition where there is a reasonable expectation of long-term survival without severe disability. Cardiac function must be adequate, as VV ECMO provides no direct cardiac support. Adult ECMO outcomes for respiratory

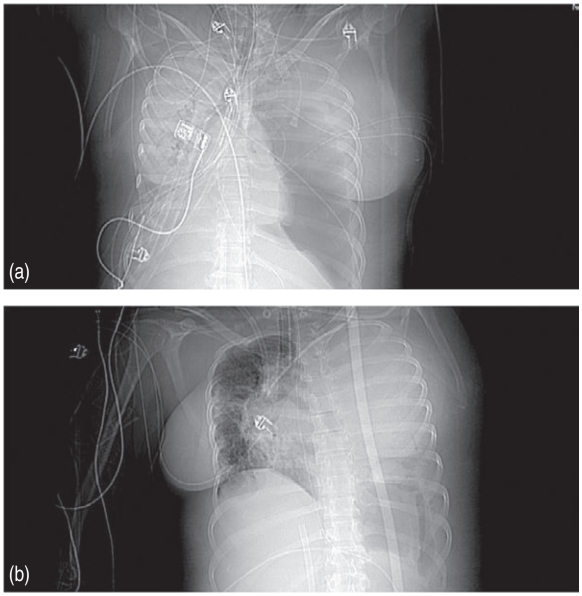

Figure 41.1.1 VV ECMO for severe respiratory failure secondary to influenza. The patient was commenced on VV ECMO urgently following the development of a tension pneumothorax during mechanical ventilation, which resulted in a cardiac arrest. (a) An extensive left-sided pneumothorax despite two intercostal catheters on day 1 of VV ECMO support with extensive right-sided consolidation. By day 8 (b) the pneumonitis had resolved and the patient could be weaned from extracorporeal gas exchange despite the development of extensive left-sided haemothorax during ECMO support, which resulted in lung necrosis (noted at thoracotomy) and ultimately death.

support from case series from specialised centres suggest that outcomes are improving.[16,17] Increasing clinical experience with ECMO support has helped define conditions that are more likely to be associated with successful outcome.[18]

Conditions where the use of VV ECMO is commonly associated with recovery and favourable outcomes (age <70) despite severe respiratory failure are:

- ARDS with primary lung injury from infection,[19] aspiration or direct trauma
- primary graft dysfunction following lung transplantation[20]
- pulmonary vasculitis (Goodpasture's, ANCA-associated, autoimmune).

Conditions where recovery is unlikely with the use of VV ECMO as a rescue therapy in the event of severe respiratory failure are:

- respiratory failure associated with long-term immunosuppression (heart, renal, bone marrow transplant recipients, HIV, graft-versus-host disease)
- respiratory failure associated with malignancy[21]
- chronic lung transplant rejection[22]
- severe septic shock where multiple advanced organ failure and purpura are present prior to the initiation of ECMO.

ECMO is also used as a bridge to lung transplantation in selected patients with advanced forms of irreversible respiratory failure.[23] ECMO should be used for known cases of irreversible end-stage respiratory failure (cystic fibrosis, interstitial lung disease, chronic obstructive airways disease) only after careful case selection by lung transplant centres.

The decision to institute ECMO for severe respiratory failure is often complex and clinical triggers and logistic factors must be considered when determining the need for and the timing of ECMO. These include:

- severity of lung injury
- adequate trial of less invasive interventions
- rate of lung injury progression
- need for inter-hospital transport
- risk of bleeding.

Clinical triggers for VV ECMO initiation in suitable patients[24] include:

- ratio of Pa_{O_2} mmHg to Fi_{O_2}<75 (Sa_{O_2}<90%)
- hypercapnia with pH<7.15 with safe mechanical ventilation settings (plateau pressure ≤35 mmHg (4.65 kPa) and tidal volume ≤6 mL/kg predicted body weight)
- extensive (3–4 quadrant) lung infiltrate consistent with acute lung injury

despite:

- optimising circulatory support (cardiac assessment with echocardiography) using inotropes or volume state therapy (where appropriate)
- trial of high PEEP (18–22) and recruitment manoeuvre (if not contraindicated)
- 2–12-hour trial of iNO or alternative pulmonary vasodilator (if available).

Rapidly progressive (6–12 hours) lung infiltrates and increasing ventilator requirements particularly in the early stages of hospital admission are often associated with a fulminate illness that reduces the time window when ECMO may be of benefit and generally favours the earlier use of ECMO.

ECMO is a mobile support that can be used across all patient transport modalities (road, fixed wing and helicopter) with very low rates of complications reported.[17,25–27] Unstable patients with severe respiratory failure requiring inter-hospital transport should be considered for ECMO.

CANNULATION FOR VV ECMO

ECMO cannulae can be safely inserted using a percutaneous dilation technique or by a surgical cut-down approach. Percutaneous dilation, which avoids skin cutting, can achieve a tight seal between skin, vessels and cannulae. This avoids bleeding associated with surgical dissection. It can also be performed quickly in a variety of settings without the need for surgical equipment or staffing.

Risks associated with 'blind' percutaneous cannulation for VV ECMO can be greatly reduced with the use of real-time vascular ultrasound and echocardiography guidance prior to and during percutaneous dilation and cannulae advancement. Ultrasound guidance and echocardiography are increasingly being adopted in numerous hospital departments and equipment is widely available. Image intensifiers can also help prevent complications associated with VV ECMO cannulation; however, they introduce additional patient transfers, require additional staffing, and may not be available in smaller centres (**Table 41.1.2**).

Utility of real-time vascular and cardiac ultrasound in VV ECMO[28] includes:

- cardiac assessment
  - cardiac function
  - detection of proximal pulmonary artery emboli
  - detection of pericardial collections and extrinsic cardiac compression
- identification of proximal vein thrombosis prior to cannulation (unilateral occlusive jugular vein thrombosis is a contraindication to contralateral jugular vein cannulation owing to the risk of cerebral oedema)
- anatomical assessment of the target vessel and branches
  - reduces carotid or femoral artery puncture
  - prevents inadvertent sapheno–femoral junction cannulation
  - identifies abnormal anatomy

Table 41.1.2 Potential major complications of cannulation for VV ECMO

COMPLICATION	CAUSE	PREVENTION
Haemorrhage	Perforation of venous system	• Real-time guidewire localisation • Ensuring guidewire continually has free movement through dilators during dilator insertion • Use 'soft' tapered dilators • Enter femoral vessel below inguinal ligament
	Cannula site bleeding	• Maintain tight skin/tissue seal with cannula • Avoid arterial puncture • Avoid transfixing the inguinal ligament • Avoid surgical dissection
Cardiac injury	Femoral dilator/cannula advanced into interatrial septum	• Image intensifier or echocardiography guidance
	Jugular dual-lumen dilator/cannula advanced into right ventricle	• Image intensifier or echocardiography guidance
Cannula malposition	Femoral access cannula in lower IVC	• Image intensifier or echocardiography guidance
	Jugular dual-lumen cannula tip in hepatic vein or right ventricle	• Image intensifier or echocardiography guidance • Adequate cannula securing

- maintenance of guidewire J-loop position in the right atrium
  - detects inadvertent guidewire entrapment ('kinking') during serial dilation
  - prevents excessive guidewire introduction and cardiac effects during cannula insertion
- guides optimal cannula tip placement
  - ensures femoral access cannulae are sited within the hepatic inferior vena cava
  - ensures return cannula sited in the right atrium without encroachment on the interatrial septum
  - ensures optimal positioning of dual-lumen VV cannula (Avalon Elite®) return port[29]
  - prevents dual-lumen VV cannula (Avalon Elite®) tip being sited in the hepatic vein.[29]

ECMO-SPECIFIC PATIENT CARE

MANAGEMENT OF CIRCUIT BLOOD FLOW SETTINGS

Rotary (constrained vortex) blood pumps generate circuit blood flow proportional to their pump speed and are afterload sensitive. In VV ECMO, afterload across the pump is low and stable provided there are no circuit obstructions. Generally, the pump operates in a pump-speed-controlled mode where pump speed is the set variable and resulting pump flow is measured. Pump speed settings are chosen to deliver sufficient circuit blood flow to achieve required oxygen delivery. Depending on patient size, oxygen consumption and lung shunt, circuit blood flow between 4 and 7 L/min will be required to achieve safe arterial oxygen saturations of over 85%, while maintaining safe lung ventilation.

MONITORING OF CIRCUIT PRESSURE

The pressure in the extracorporeal circuit becomes progressively more negative from drainage cannula tip to the inflow to the pump head. The maximal positive circuit pressure occurs at the outlet of the pump head and falls progressively to the return cannula. The oxygenator is located distal to the pump head and receives blood under positive pressure. The pressure change across the oxygenator can be measured safely and easily without introducing circuit connectors and gives an indication of clot burden within the oxygenator. One current-generation ECMO pump (Cardiohelp-HLS, Maquet) has integrated pressure monitoring of pre- and postoxygenator pressure in addition to negative-pressure monitoring at the pump head inlet.

ACCESS INSUFFICIENCY

As pump speed is increased, the negative pressure at the access cannulae inlet also becomes more negative. If venous return to the access (draining) ECMO cannula is inadequate for the degree of pump suction, venous 'suck-down' will occur and circuit blood flow will fall and become variable, usually with audible and visible effects on the inflow of the circuit (access insufficiency). This situation must be identified and rectified quickly (reducing pump speed) to prevent haemolysis and potential vascular injury.[30] Access insufficiency may prevent adequate circuit blood flow and oxygen delivery. Multi-stage access cannulae distribute the negative circuit pressure over a longer length of a vessel and deliver higher maximal blood flow than similar single-stage access cannulae.

Factors that increase the occurrence of access insufficiency include:

- femoral access cannula tip sited too low
- dual-lumen cannula not optimally sited
  - distal tip sited in the hepatic vein (instead of IVC)
  - catheter withdrawn and SVC access sited too high within the right brachiocephalic vein
- reduced venous return
  - blood or volume loss
  - vasodilation
  - raised intrathoracic or intra-abdominal pressure
- reduced venous capacitance
  - extrinsic right heart compression.

TITRATION OF FRESH GAS FLOW TO THE OXYGENATOR

Fresh gas flow (FGF) to the oxygenator maintains the diffusion gradients for O_2 delivery to, and CO_2 removal from, the circuit blood. Fresh gas flow can be composed of dry air–oxygen mix or pure O_2. The partial pressure of O_2 in the FGF determines the postoxygenator blood partial pressure O_2. The FGF rate determines the partial pressure of CO_2 in the postoxygenator and its rate is chosen to achieve a desired Pa_{CO_2} in the patient's arterial blood.

LUNG VENTILATION

Non-injurious lung ventilation is a primary goal of ECMO support in respiratory failure. Non-pulmonary gas exchange facilitates low pressure and volume strategies and a number of lung ventilation modes have been advocated during the different phases of ECMO support. PEEP levels are chosen to maintain lung aeration. Peak lung pressures can easily be maintained below 30 cmH_2O with ECMO support. Tidal volumes may be negligible despite normal distending pressures and remain much less than the anatomical dead space of the lung during ECMO support. Improving lung compliance and the return of physiological tidal volume herald lung recovery from acute lung injury.

WEANING

As lung recovery occurs it is standard to wean ECMO gas flow until it is off, at which point the patient is no longer receiving extracorporeal support. Cannulae are generally removed after a period of time off gas flow (usually 2–24 hours). There is no need to wean circuit blood flow below 3 L/min during weaning, which reduces the need for additional anticoagulation. Percutaneously inserted venous cannulae can be removed at the bedside (off anticoagulation) and skin sites compressed for 20 minutes.

In general, ECMO weaning and decannulation are performed in advance of airway extubation. Where ECMO is used in chronic respiratory failure conditions, it can be advantageous to extubate patients during ECMO support in order to maintain wakefulness and avoid the complications of sedation. Ambulant ECMO is highly desirable for cystic fibrosis patients being bridged to transplantation to maintain secretion clearance.[31] Whether ambulant ECMO provides additional benefit for patients with acute respiratory failure is currently uncertain.

ANTICOAGULATION

Anticoagulation for ECMO is given to reduce the rate of clot formation within the circuit, and reduce clot formation associated with cannulae.[32] Clotting is often seen in low-flow regions of the oxygenator but is not an indication for circuit change. It is generally accepted that systemic anticoagulation with heparin should be provided for all patients on ECMO *provided there is no bleeding and there is no anticipated or recent surgery*. Anticoagulation practices are based on patient bleeding risk profiles and VV ECMO can be successfully run for days without anticoagulation in order to arrest bleeding. Essential surgery can also be performed during ECMO support.[33]

ECMO-SPECIFIC PATIENT COMPLICATIONS

Prevention of complications is fundamental to successful ECMO care. Patients are at increased risk of bleeding, particularly from the injured lung, and have an increased risk of haemolysis. VV ECMO can provide great stability to the patient with severe respiratory failure, but may also induce dangerous complications if the circuit is breached (accidental decannulation, circuit rupture) or the blood pump fails. Staff training and beside resources to standardise decision-making are important components of successful ECMO programmes. Avoiding excessive sedation, provision of timely pressure care and physical therapy during VV ECMO support are becoming routine.

BLEEDING

Bleeding remains the main complication of ECMO; however, many sources of bleeding can be prevented. Cannulation site bleeding should be uncommon in VV ECMO if optimal percutaneous cannulation techniques are used and surgical dissection is avoided. Pulmonary bleeding is a frequent cause of death during VV ECMO support for respiratory failure.[34] Insertion of intercostal catheters during ECMO is an extremely high-risk intervention and should not be performed unless no other alternative remains. In particular, intercostal catheters should not be inserted for pneumothoraces or pleural fluid drainage unless they are massive or cause haemodynamic collapse.[35] During VV ECMO, pneumothoraces may be managed by increasing ECMO support and reducing pulmonary ventilation, without the need for

tube insertion. Fibrinolysis and secondary consumptive coagulopathy can occur during ECMO particularly with older circuits and induce generalised bleeding. Monitoring of fibrinogen and D-dimer levels and elective ECMO circuit changes are required to control this process.

Therapies for managing severe bleeding during ECMO support are given in Subchapter 41.1.2 ECMO for cardiac failure.

HAEMOLYSIS

Haemolysis (repeated plasma free Hb >0.1g/dL) is extremely uncommon with current-generation circuits; however regular monitoring of plasma free Hb is still routine in many centres. Severe haemolysis (plasma free Hb >1.0 g/L or with hyperkalaemia or red urine) suggests pump head thrombosis and must be treated with an urgent circuit change.

AIR EMBOLISM

Air will rapidly enter the circuit during pump operation if there is any breach in the negative pressure region of the circuit. Taps and other potential breaches on the negative (pre-pump) side of the circuit should be avoided. Air that enters the circuit will de-prime the pump head (reducing circuit flow), accumulate in the oxygenator and may reach the return line and cause patient air embolism. Staff education and circuit design are essential preventative measures. De-airing the circuit following air embolism is technically challenging.

CLINICAL TRIALS

ECMO has been used since 1966 as a rescue therapy for severe acute respiratory failure that is refractory to mechanical ventilation.[36] The process of establishing the clinical efficacy for this practice has a long and fascinating history owing to the unique ethical[37] and logistical challenges inherent in this form of support and the patient populations with this disease. In the 1970s and 1980s, uncontrolled observational reports suggested clinical benefits with the use of extracorporeal support, but these were not realised in subsequent randomised controlled trials (RCTs).[38,39]

In 2001, the CESAR trial,[40] a prospective randomised adult ECMO trial conducted in the United Kingdom, commenced enrolment. The results were published in 2009, and the intention-to-treat analysis showed that significantly more patients allocated to consideration for treatment including ECMO survived to 6 months without disability compared with those allocated to conventional management. This result represented a relatively large treatment effect, albeit with borderline precision and with a sample size that was less than initially planned. Reasonable concerns with regard to the basis of the efficacy, the quality of respiratory care in the control arm and the generalisability of the findings outside the UK have been raised.[41]

Currently, a subsequent French multinational adult ECMO trial for severe respiratory failure is under way. Mechanical ventilation strategies for both arms demand protective lung ventilation (ClinicalTrials.gov Identifier: NCT01470703).

41.2 ECMO for cardiac failure

Mortality from cardiogenic shock and refractory ventricular fibrillation is very high and frequently cannot be adequately managed with medical therapy. Veno-arterial extracorporeal membrane oxygenation (VA ECMO) is a rapidly deployable, short-term system for complete or partial support of the circulatory system. It can allow time for reversible forms of cardiac failure to recover and can prevent end-organ damage from under perfusion. It can provide organ support before, during or after therapeutic cardiovascular procedures. In patients with advanced chronic heart failure and secondary acute end-organ injury, it can provide a bridging support to longer-term devices and allow time for thorough case selection.

Traditionally, veno-arterial (VA) ECMO has been employed by surgical staff in the operative setting, but progressively it is being applied in non-operative settings by a number of trained specialists. Although previously predominately used as a neonatal and paediatric support, it is increasingly being used in adults.

Additional explanations of ECMO are given in the section on ECMO for respiratory support.

DEFINITIONS

MODE

Veno-arterial ECMO (VA ECMO) is the ECMO *mode* used for cardiac support. Blood is removed from the right atrium and adjacent veins and then returned to the aorta, bypassing the native heart and lungs. VA ECMO comprises a specialised *access cannula* to drain venous blood, an external circuit (*tubing*), a gas exchange device (*oxygenator*) where blood becomes enriched with oxygen and has carbon dioxide removed, and a *return cannula* through which circuit blood returns to the arterial system. A pump drives the circuit blood flow and heat exchange is possible. A *fresh gas flow* is delivered to the oxygenator. ECMO circuit flows are adequate to provide complete systemic perfusion (5–7 litres of blood per minute); however, it may not provide specific left ventricular 'unloading'.[1] Percutaneous cardiopulmonary bypass is another term for VA ECMO.

In veno-pulmonary artery (VPA) ECMO, venous blood is accessed from a large central vein and returned to the pulmonary arterial system via a specialised surgical conduit after it has passed through the oxygenator. It provides short-term right ventricular (and respiratory) support in the intraoperative setting following left ventricular assist device insertion.[2]

CONFIGURATION

The *configuration of VA ECMO* determines the manner in which the ECMO circuit interacts with the native circulation. Cannulae insertion sites and the tip positions define configuration. Broadly, there are three adult VA ECMO configurations (**Table 41.2.1**):

- femoro-femoral
- jugulo-subclavian[3]
- central (including V-PA ECMO).

DISTINCT FROM ECMO

Short-term *ventricular assist devices (VAD)* may employ similar cannulae, circuit tubing and pumps to ECMO, but do not include an oxygenator and are configured to provide single ventricular mechanical support only. Left VAD (LVAD) is configured using a left heart access cannula with an aortic return cannula. Right VAD (RVAD) is configured using right heart access with a pulmonary artery return. Biventricular VAD support configurations (BiVAD) are distinct from VA ECMO.

BLOOD FLOW PRINCIPLES

VA ECMO blood flow bypasses the native heart and lungs. Two arterial circulations may be identifiable during VA ECMO support. In contrast to VV ECMO, recirculation is not seen during VA ECMO support.

NATIVE CARDIAC OUTPUT

Native cardiac output produces pulsatile pulmonary and aortic blood flow during VA ECMO support. Cardiac function can vary from absent to near-complete during different phases of VA ECMO support. Oxygen and carbon dioxide (CO_2) gas tensions of the native cardiac output will reflect the pulmonary gas exchange and predominately be delivered to the coronary and cephalic circulations. Because CO_2 is only delivered to the lung by the native cardiac output, through the pulmonary circulation, airway CO_2 excretion is also indicative of native cardiac output.

CIRCUIT BLOOD FLOW

The distribution of the returning VA ECMO circuit blood within the arterial tree is dependent on the particular VA ECMO configuration, ECMO circuit blood flow and the native cardiac output. The gas tensions in the ECMO circuit blood flow reflect gas exchange across the oxygenator. During complete VA support, ECMO circuit blood flow provides all systemic perfusion and arterial gas tensions will be similar to post-oxygenator readings. In this state, the arterial waveform is non-pulsatile. As cardiac function returns, pulsatility will be seen and arterial gas tensions will reflect the proportion of native and circuit blood flow reaching the sampling site.

Table 41.2.1 Configurations of VA ECMO

CONFIGURATION	INSERTION SITE	CANNULA TIP POSITION	CANNULA TYPE AND SIZE	ADVANTAGES/ DISADVANTAGES
Femoro-femoral ECMO (Fem-fem)	*Access:* Femoral vein *Return:* Common femoral artery (with distal perfusion cannula)	*Access:* Right atrium *Return:* Iliac artery or distal aorta	*Access:* Multi-stage (19–25F) *Return:* Single stage (15–21F)	*Advantages:* Quick to deploy Surgery not required *Disadvantages:* High rate of limb ischaemia if distal perfusion cannula not used Unable to ambulate Allows cephalic differential hypoxaemia
Jugulo-subclavian ECMO[3]	*Access:* Right jugular vein *Return:* Right subclavian artery (tunnelled)	*Access:* Right atrium *Return:* Right subclavian artery (T-graft)	*Access:* Short single stage (19–23F) *Return:* Specialised graftable	*Advantages:* Allows ambulation and unrestricted sitting Reduces cephalic differential hypoxia *Disadvantages:* Right arm swelling or axillary plexus injury
Central ECMO (atrio-aortic)	*Access:* Sternotomy or tunnelled subcostally *Return:* Sternotomy or tunnelled subcostally	*Access:* Right atrium via atrial appendage *Return:* Proximal ascending aorta	Standard by-pass cannulae (access and return) inserted via sternotomy (36–46F) *or* Specialised long-term surgical (graftable) arterial cannula and malleable atrial cannula (tunnelled with closed sternum) (36–46F)	*Advantages:* Accessible during cardiac surgery Large cannula and lower circuit resistance *Disadvantages:* Surgical site bleeding Restricted patient movement and pressure area care Respiratory effects of sternotomy
Femoro-pulmonary artery ECMO (VPA ECMO)[2]	*Access:* Femoral vein *Return:* Tunnelled via chest wall	*Access:* Right atrium *Return:* Main pulmonary trunk	*Access:* Multi-stage (19–25F) *Return:* Specialised surgical graft and short single stage 19F cannula	*Advantages:* Maintains full LVAD flows Provides respiratory and right heart support Removal without surgery *Disadvantages:* Pulmonary artery vascular graft remains in situ

DIFFERENTIAL OXYGENATION DURING VA ECMO

A significant lung shunt in association with an improving native cardiac output can result in large degrees of differential oxygenation in patients supported with peripheral VA ECMO. With femoral arterial VA ECMO return, highly oxygenated blood is preferentially distributed to the caudal regions as native cardiac output improves while deoxygenated blood leaving the left ventricle predominately perfuses the coronary and cephalic circulations. For this reason, patients on peripheral VA ECMO should have arterial oxygenation monitored via the right arm.

CIRCUIT PRESSURE

The pressure gradient across a VA ECMO circuit is greater than in VV ECMO owing to the physiological systemic arteriovenous pressure. Consequently, in VA ECMO, it is normal to require higher pump speeds to achieve full support, and pressure monitoring in the circuit (see VV ECMO) will record higher pressures at the membrane and in the return line. Such high ECMO

circuit pressure may limit the ability for the provision of continuous renal replacement via the ECMO circuit.

INDICATIONS AND PATIENT SELECTION

VA ECMO is indicated for life-threatening forms of cardiac failure where the risks of less invasive support are considered greater than the risks of ECMO and there is a reasonable expectation of long-term survival without severe disability. Currently ECMO is generally considered in patients up to the age of 70 without other chronic organ failures or terminal illnesses.

Common indications for VA ECMO support with a reasonable chance (>50%) of subsequent recovery and favourable outcomes include:

- acute fulminate myocarditis[4–6]
- cardiomyopathy (bridge to VAD)[7]
- AMI-cardiogenic shock prior to multiple organ failure[8]
- drug overdose with profound cardiac depression or arrhythmia[9–11]
- pulmonary embolism with cardiogenic shock[12]
- primary graft failure: post heart[13,14]/heart–lung transplant.

The use of ECMO for refractory 'in-hospital' cardiac arrest (with ECMO commenced within 60 minutes)[15–17] is associated with recovery rates of approximately 30% (alive to discharge), which both may be superior to standard treatment and may be improving over time.

Conditions where recovery is rare (<25%) despite the use of VA ECMO as a rescue therapy include:

- adult cardiogenic shock with established multi-organ failure
- adult septic shock with severe myocardial depression and multi-organ failure
- heart transplant with chronic rejection
- 'out of hospital' and prolonged cardiac arrest.[18]

Cardiac and vascular lesions that prevent the successful application of VA ECMO are:

- aortic dissection
- severe aortic regurgitation[19]
- severe mitral regurgitation.

ECMO is also used as a bridge to VAD and heart transplantation in selected patients with advanced forms of irreversible cardiac failure and pulmonary hypertension. Decisions regarding the choice of mechanical support modalities in this population should involve specialised transplant services.

CLINICAL TRIGGERS FOR VA ECMO INITIATION IN SUITABLE PATIENTS WITH CARDIOGENIC SHOCK

Due to the rapid onset of end-organ damage with cardiogenic shock and refractory arrest, the timing of VA ECMO initiation is critical in patient outcome. A guide to the clinical triggers and logistic factors to be considered when determining the timing of ECMO for a deteriorating patient with cardiogenic shock is given below:

- pharmacological support of cardiac index and blood pressure is likely to exacerbate the underlying primary cardiac illness (e.g. AMI-cardiogenic shock or recurrent VF)
- cardiac index and blood pressure inadequate despite pharmacological support:
  - moderate- or high-dose inotropes (epinephrine (adrenaline) >0.3 μg/kg/min equivalent) in combination with an IABP, vasopressors and positive-pressure ventilation for predominately left ventricular failure
  - moderate- or high-dose inotropes (epinephrine (adrenaline) >0.3 μg/kg/min equivalent) in combination with pulmonary artery vasodilator and/or systemic vasopressors for predominately right ventricular failure
- onset of secondary hepatic, renal or skin ischaemia despite pharmacological support
- lactate >5 mmol/L and rising despite pharmacological support.

VA ECMO is a mobile support that can be used across all patient transport modalities (road, fixed wing and helicopter) with very low rates of complications reported.[20] Time delays incurred with ECMO retrieval must be considered during assessment.

CANNULATION FOR VA ECMO

ECMO cannulae can be safely inserted using a percutaneous dilation technique or by a surgical cut-down approach. Percutaneous dilation, which avoids skin cutting, can achieve a tight seal between skin and cannulae. This avoids bleeding associated with surgical dissection. It can also be performed quickly in a variety of settings without the need for surgical equipment or staffing.[21]

Risks associated with 'blind' percutaneous cannulation for VA ECMO can be greatly reduced with the use of real-time vascular ultrasound and echocardiography guidance prior to and during percutaneous dilation and cannulae advancement. Ultrasound guidance and echocardiography are increasingly being adopted in numerous hospital departments and equipment is widely available. Image intensifiers can also help prevent complications associated with VV ECMO cannulation; however, this introduces additional patient transfers, requires additional staffing and may not be available in smaller centres.

UTILITY OF REAL-TIME VASCULAR AND CARDIAC ULTRASOUND IN VA ECMO[22]

- Cardiac assessment
  - Cardiac and valvular function

  - Detection of proximal pulmonary artery emboli
  - Detection of pericardial collections and extrinsic cardiac compression
  - Presence of aortic disease
  - Detection of intracardiac thrombosis
- Anatomical assessment of the target vessel and branches
  - Prevents inadvertent sapheno-femoral junction venous cannulation
  - Prevents inadvertent profunda femoris artery injury (arterial cannulation)
  - Identifies abnormal anatomy
- Immediate confirmation of needle entry in vein and confirmation of arterial cannulation prior to dilation (required during pulseless resuscitation)
- Maintenance of guide-wire J-loop position during dilation
  - Detects inadvertent guide-wire entrapment ('kinking') during serial dilation
  - Prevents excessive guide-wire introduction and cardiac effects during cannula insertion
- Guides optimal cannula tip placement
- Weaning study from VA ECMO[23]
  - LVOT blood flow assessment.

ECMO-SPECIFIC PATIENT CARE

ASSESSMENT OF NATIVE CARDIAC OUTPUT

This is approximately assessed at the bedside using the pulsatility of the arterial blood pressure and end-tidal CO_2 trace (**Fig. 41.2.1**). It can be measured from velocity–time integration of blood flow through the left ventricular outflow tract with echocardiography, but not by thermodilution due to partial loss of indicator into the ECMO circuit. Native cardiac output must be assessed regularly during VA ECMO support to titrate lung ventilation in order to avoid gross abnormalities in lung V/Q ratios. It is also important in assessing the adequacy of overall systemic perfusion.

MANAGEMENT OF CIRCUIT BLOOD FLOW SETTINGS

VA ECMO circuit blood flow settings are primarily chosen to achieve adequate overall systemic perfusion. ECMO circuit flow, which is continually measured, in combination with the native cardiac output equate to the total body blood flow. Adequate mechanical systemic perfusion allows inotropic support to be weaned or ceased and lowers myocardial work. Adequate mechanical circulatory support can allow safe performance of high-risk percutaneous cardiac procedures.

ACCESS INSUFFICIENCY

Access insufficiency can occur in all modes of ECMO and is described in the section on ECMO for respiratory failure.

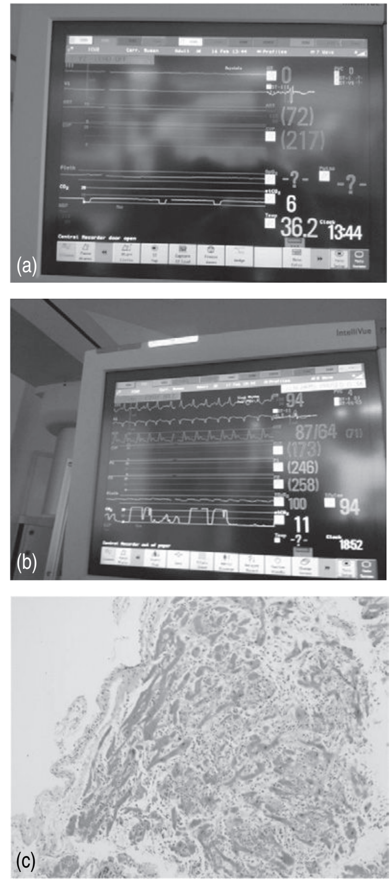

Figure 41.2.1 The stages of cardiac support with VA ECMO for a case of severe lymphocytic myocarditis. Arterial pulsatility was lost on day 1 following ECMO initiation for cardiogenic shock. On day 2 (a) after ECMO support the asystole and ventricular standstill were frequently seen for hours. By day 3 (b), pulsatility and end-tidal CO_2 signals returned with cardiac recovery following immunosuppressive therapy. The patient was decannulated by day 7 and extubated by day 9 and made a full recovery. (c) Cardiac biopsy on day 1 showing heavy lymphocytic infiltration.

TITRATION OF FRESH GAS FLOW TO THE OXYGENATOR

Fresh gas flow (FGF) to the oxygenator maintains the diffusion gradients for O_2 delivery to, and CO_2 removal from, the circuit blood (see ECMO for respiratory failure). Where VA ECMO provides partial circulatory support, significant CO_2 clearance will occur via the lungs and low rates of FGF to the oxygenator will be required to prevent respiratory alkalosis. Inadequate FGF during VA ECMO will prevent oxygenation of venous blood within the ECMO circuit and impose an extrapulmonary right-to-left shunt.

LUNG VENTILATION

Many patients on peripheral VA ECMO support do not require mechanical ventilation or sedation, in contrast to patients configured with central VA ECMO support. Positive-pressure ventilation is beneficial in the management of pulmonary oedema, which may develop during VA ECMO support where left ventricular failure is more severe than right ventricular failure. Mechanical lung ventilation may also form part of the management of a lung shunt, which becomes evident during VA ECMO as native cardiac function returns (see below).

PREVENTION OF DISTAL LIMB ISCHAEMIA

All patients with a peripheral ECMO arterial return catheter should have a *distal perfusion cannula* inserted to prevent limb ischaemia occurring as a result of the occlusive and compressive effects of the return cannula.[24] The presence of normal lower limb perfusion should not prevent the insertion as limb ischaemia may progress quickly. Distal perfusion cannulae are not required for specialised surgical cannulation using a 'T' graft.

DIFFERENTIAL HYPOXIA

Differential hypoxia occurs when hypoxaemic blood from the pulmonary circulation is ejected from the left heart while fully oxygenated blood enters the arterial circulation from the ECMO circuit. It develops during peripheral VA ECMO support as cardiac function returns when a large intrapulmonary shunt is present, and its development indicates cardiac recovery. It is not seen in central VA ECMO as the ECMO circuit blood enters the arterial tree at the proximal aorta. Its development can be anticipated in known cases of combined severe respiratory and cardiac failure, or it may only become apparent following successful resuscitation. Right subclavian artery return configuration will reduce the cerebral effects in peripheral ECMO, compared with femoral return.

Management includes weaning off any inotropic agents, treating the lung shunt with positive-pressure ventilation, PEEP, bronchoscopy, and inhaled nitric oxide if appropriate. Increasing the ECMO circuit blood flow should reduce the proportion of venous return able to reach the lungs. If severe hypoxaemia persists (Sa_{O_2}<85%) despite other measures, consideration of changing the mode of ECMO support from VA to VV should be considered.

LOSS OF PULSATILITY

The ability of the heart to open the aortic and pulmonary valves and contribute to cardiac output may be temporarily lost in severe forms of cardiac failure. The progressive loss of pulsatility during VA ECMO support may indicate extrinsic cardiac compression or progressive cardiac failure and urgent echocardiography is required to establish the cause. Extrinsic cardiac compression from bleeding is more common in the postoperative cardiac setting and must be managed surgically.

Severe myocardial failure with loss of pulsatility is associated with increased risk of intracardiac thrombosis with arterial embolisation. Management is aimed at preservation of some intracardiac blood flow and higher anticoagulation targets. Increased inotropic support, reduction in arterial pressure and reduced ECMO circuit blood flow may improve cardiac blood flow.

MANAGEMENT OF LEFT VENTRICULAR FAILURE

Pathology that results in a predominance of left ventricular heart failure, compared with right ventricular failure (e.g. massive left ventricular AMI), the presence of aortic or mitral valve regurgitation or high mean arterial pressure, can result in progressive distension of the left ventricle, and congestion of the pulmonary circulation and lungs during VA ECMO support. Non-surgical options for control of LVF during VA ECMO support include positive-pressure ventilation and high PEEP, reduction in mean arterial pressure and reducing or ceasing inotropic support. Surgical options include the addition of a left heart drainage cannula to the circuit, conversion from ECMO to a LVAD, or the use of minimally invasive transaortic valve axial pumps.[25–28]

PREVENTION AND MANAGEMENT OF BLEEDING

Prevention of bleeding remains the greatest challenge for ECMO patient care and preventative strategies are given in Chapter 41.1.1 on VV ECMO for respiratory failure. Surgical site bleeding is the most common cause of severe bleeding in VA ECMO. The management of severe bleeding during ECMO commonly involves the following responses and involvement of surgeons and specialist haematology support:

INITIAL RESPONSE TO BLEEDING

- Heparin should be ceased and not be recommenced until all bleeding has stopped for 12–24 hours.
- Aggressively replace all clotting element deficiencies:
  - cryoprecipitate until fibrinogen >1.5 g/dL
  - platelets until count is >80 000 and normal maximal amplitude (MA) on a thromboelastogram (TEG)
  - FFP or human prothrombin complex (Prothrombinex™) until INR is <1.3 and there is normal reaction (R) time on TEG.

ADDITIONAL TREATMENTS IF THERE IS SEVERE OR REFRACTORY BLEEDING

- Fibrinolytic treatment[29]
- Factor VIIa treatment[30,31]
- Surgery.

Protamine is not given to bleeding patients with heparin-bonded circuits owing to the risk of acute circuit thrombosis.

ANTICOAGULATION

Anticoagulation for ECMO in the setting of severe cardiac failure reduces the risk of clot formation within the heart, extracorporeal circuit and cannulae. Heparin is the first-line therapy despite both its limitations and the spectrum of heparin-induced thrombocytopenia and thrombosis (HITTs). Most centres target anticoagulation values below those for management of thromboembolic disease. Definitive recommendations for the titration of heparin therapy are lacking. Activated clotting time (ACT), activated partial thromboplastin time (APTT) and thromboelastograms (TEG) are all used in different centres, but there remains poor correlation between tests and no relevant outcome data on which to base recommendations.[32]

HITTs is a rare, but potentially devastating, complication of heparin therapy during ECMO support. Case reports of successful management with the use of intravenous direct thrombin inhibitors (heparin ceased) exist.[33–35]

WEANING AND DECANNULATION

VA ECMO for cardiac failure generally runs for 3–12 days, which allows time for assessment of cardiac recovery or planning for alternative support if indicated. Cardiac recovery is suggested by improving pulsatility with low or no inotropic support. A formal echocardiographic weaning study is required to assess suitability for decannulation.[23] During a weaning study, haemodynamics, ventricular function and native cardiac output are monitored and measured at progressively lower ECMO circuit blood flow rates (to 1 L/min in adults). Adequate recruitment in the native cardiac output during weaning and haemodynamic stability support the decision to schedule decannulation. Central and peripheral configurations of VA ECMO require surgical repair of the artery after decannulation.

EXPECTED PATIENT OUTCOMES

The clinical effectiveness of VA ECMO for cardiogenic shock and refractory VF has not been evaluated in prospective clinical trials. A number of larger case series and cohort studies allow some assessment of the expected outcomes in the more common patient groups that received VA ECMO support. Successful patient outcomes from a complex intervention are likely to occur in centres with clinical leadership, training and competency programmes, adequate protocols and resources and governance programmes. The application of ECMO before end-organ damage and use in selected patients with either reversible conditions or suitable for longer-term treatment options will also probably be associated with improved outcomes.[36]

In addition the Extracorporeal Life Support Organization, which was established in 1989, maintains a registry of ECMO use in registered ECMO centres around the world. The ELSO registry provides annual outcome data for members (see www.elsonet.org) in addition to educational programmes and resources.

Acute gastrointestinal bleeding

Joseph JY Sung

Acute gastrointestinal (GI) bleeding is a common admission to the intensive care unit (ICU) and a major cause of morbidity and mortality. Peptic ulcer disease accounts for 75% of upper GI bleeding.[1,2] Bleeding from varices, oesophagitis, duodenitis and Mallory–Weiss syndrome each account for between 5% and 15% of cases. About 20% of GI bleeding arises from the lower GI tract. Common aetiological causes for GI bleeding are listed in **Box 42.1**. Mortality from upper GI bleeding has remained at approximately 10% for decades, but recent reports suggest that mortality from ulcers bleeding has fallen substantially, to about 5%.[3] Furthermore, the majority of cases died of causes unrelated to bleeding, but rather to cardiopulmonary or multi-organ failure.[4] This observation emphasises the benefit of good supportive care in the intensive care unit for patients presenting with gastrointestinal bleeding. Variceal bleeding has a much higher mortality of about 30%. Risk factors for mortality include old age, associated medical problems, coagulopathy and the magnitude of bleeding.

UPPER GASTROINTESTINAL BLEEDING

CLINICAL PRESENTATION

The patient may or may not present with a history of upper GI problems. There may be pain but bleeding ulcers can be painless, especially in elderly patients and users of non-steroidal anti-inflammatory drugs. Frequently, the common symptoms of hypovolaemia such as tachycardia, pallor, sweating, cyanosis, mental confusion and oliguria are present, especially in massive GI bleeding. A history of vomiting and retching preceding haematemesis suggests Mallory–Weiss syndrome.

Haematemesis and melaena are the most common presentations of acute upper GI bleeding. Haematochezia is the passage of bright red or maroon blood from the rectum, in the form of pure blood or admixed with stool. It usually represents a lower intestinal source of bleeding, but can also be a feature of massive upper GI bleeding.

INVESTIGATION

ENDOSCOPY OR BARIUM STUDY

As history and physical examination are seldom useful in identifying the specific site of bleeding, investigations are necessary in most cases of GI bleeding. Endoscopy has replaced barium studies as the investigation of choice and recent studies show that endoscopy should be offered within 24 hours of presentation to hospital to provide optimal clinical outcome.[5]

Endoscopy is preferred to barium X-rays for the following reasons:

- Endoscopy allows more precise identification of the site and nature of bleeding.
- Endoscopic appearance often predicts the risk of recurrent bleeding from ulcer and varices (see below).
- Lesions such as gastritis, portal hypertensive gastropathy and duodenitis are difficult to diagnose by barium X-ray.
- Treatments such as injecting ulcers may be instigated during endoscopy (see below).
- Barium X-ray is notoriously unreliable in patients with previous gastric surgery.

However, endoscopy is not without potential problems and in particular can induce serious hypoxia in patients with cardiorespiratory diseases. Careful supervision with continuous monitoring of blood pressure, pulse and oxygen saturation with a pulse oximeter is mandatory. Oxygen should be administered by nasal cannula when necessary.

ANGIOGRAPHY

Angiography is seldom used for the diagnosis of upper GI bleeding. Theoretically, when the bleeding is very brisk (greater than 0.5 mL/minute), and obscures the endoscopic view, angiography may help to identify the sources of bleeding and may sometimes be used to embolise the bleeding point. In practice, however, most patients with this degree of haemorrhage should be considered for emergency laparotomy.

MANAGEMENT OF NON-VARICEAL UPPER GI BLEEDING

The goals of managing a patient with acute GI bleeding are, first, to resuscitate, second, to control active bleeding and, third, to prevent recurrence of haemorrhage.

RESUSCITATION

Blood and plasma expanders should be given through large-bore intravenous cannulae. Vital signs should be

Box 42.1 Common causes of acute gastrointestinal bleeding

Upper gastrointestinal bleeding
Peptic ulcers (DU : GU 3 : 1)
Varices (oesophageal varices : gastric varices 9 : 1)
Portal hypertensive gastropathy
Mallory–Weiss syndrome
Gastritis, duodenitis and oesophagitis
Lower gastrointestinal bleeding
Diverticular bleeding
Angiodysplasia and arteriovenous malformation
Colonic polyps or tumours
Meckel's diverticulum
Inflammatory bowel diseases

DU=duodenal ulcer; GU=gastrointestinal ulcer.

closely monitored. In patients with hypovolaemic shock, central venous pressure and hourly urine output should also be observed (see Ch. 15). Following adequate resuscitation, management is directed at identifying the lesion and distinguishing the high-risk patient, who is likely to require early endoscopic or surgical treatment.

THE HIGH-RISK PATIENT

Significant GI bleeding is indicated by syncope, haematemesis, systolic blood pressure below 100 mmHg (13.3 kPa), postural hypotension and a blood transfusion requirement of more than 4 units of blood in 12 hours, to maintain blood pressure. Patients over 60 years old and with multiple co-morbidities are at even higher risk.[3] Those admitted for other medical problems (e.g. heart or respiratory failure, or cerebrovascular bleed) and who have GI bleeding during hospitalisation also have a higher mortality.

THE HIGH-RISK ULCER

Peptic ulcers that are actively bleeding or have bled recently may show stigmata of haemorrhage on endoscopy. These include localised active bleeding (i.e. pulsatile, arterial spurting or simple oozing), an adherent blood clot, a protuberant vessel or a flat, pigmented spot on the ulcer base. Stigmata of haemorrhage are important predictors of recurrent bleeding (**Table 42.1**). The proximal postero-inferior wall of the duodenal bulb and the high lesser curve of the stomach are common sites for severe recurrent bleeding, probably owing to their respective large arteries (gastroduodenal and left gastric arteries).

Table 42.1 Stigmata of haemorrhage and risk of recurrent bleeding in peptic ulcers

STIGMATA OF HAEMORRHAGE	% RECURRENT BLEEDING
Spurter or oozer	85–90
Protuberant vessel	35–55
Adherent clot	30–40
Flat spot	5–10
None	5

TREATMENT

Pharmacological control

Acid-suppressing drugs such as H_2-receptor antagonists and proton pump inhibitors are very effective drugs to promote ulcer healing. An acidic environment impairs platelet function and haemostasis. Therefore, reducing the secretion of gastric acid should reduce bleeding and encourage ulcer healing. A recent study has shown that potent acid suppression using intravenous proton pump inhibitors reduces recurrent bleeding after endoscopic therapy.[6] Proton pump inhibitors should be recommended in high-risk peptic ulcer bleeding patients as an adjuvant to endoscopic therapy. In contrast, antifibrinolytic agents such as tranexamic acid have not been effective in reducing the operative rate and mortality of acute GI haemorrhage. Recent studies show that, in patients at high risk of recurrent bleeding, pharmacological control without endoscopic haemostasis is inadequate.[7] Thus a combination of endoscopic and pharmacological therapy offers the best therapy for ulcer-bleeding patients.[8,9]

Endoscopic therapy

Most patients with acute upper GI haemorrhage stop bleeding spontaneously and have an uneventful recovery. No specific intervention is required in these patients. Endoscopic haemostasis should be used in patients with a high risk of persistent or recurrent bleeding. In the last two decades, endoscopic haemostasis, with its high efficacy and low morbidity, has resulted in a dramatic decrease in emergency surgery, and has reduced the mortality of ulcer bleeding. The three most popular methods of haemostasis are as follows.

Epinephrine (adrenaline) injection

Endoscopic injection of epinephrine (1:10 000 dilution) at 0.5–1.0 mL aliquots (up to 10–15 mL) into and around the ulcer bleeding point has achieved successful haemostasis in over 90% of cases.[8] Debate exists as to whether the haemostatic effect is a result of local tamponade by the volume injected or vasoconstriction by epinephrine. Absorption of epinephrine into the systemic circulation has been documented, but without any significant effect on the haemodynamic status of the patient.[10] Epinephrine injection is an effective, cheap, portable and easy-to-learn method of haemostasis, and has acquired worldwide popularity.

Coaptive coagulation

This method uses direct pressure and heat energy (heater probe) or electrocoagulation (bipolar coagulation probe (BICAP)) to control ulcer bleeding. The depth of tissue injury induced by these devices is minimal, as the bleeding vessel is tamponaded prior to coagulation. The overall efficacy of the epinephrine injection, heater probe and BICAP probe methods are comparable.[11] Occasionally, it is not possible to obtain a view en face of the bleeding ulcers, particularly those on the lesser curve or on the posterior wall of the duodenal bulb. In these situations, direct pressure cannot be applied, and the failure rate of coaptive coagulation tends to be higher.

Haemoclips

Endoscopic clipping of a bleeding vessel is an appealing alternative treatment that has gained popularity in recent years. The advantage of haemoclips over thermocoagulation is that there is no tissue injury induced and hence the risk of perforation is reduced. Studies comparing haemoclips with injection and thermocoagulation have shown favourable results.[12,13] However, the application of haemoclips in certain sites, for example lesser curve, gastric fundus and posterior wall of the duodenum, is technically difficult. Loading of clips on to the application device is cumbersome and time-consuming and transfer of torque from the handle to the tip of the device is limited.

SURGERY

Surgery remains the definitive method of stopping haemorrhage, but there is little agreement on the exact indications and best timing for surgical intervention. These issues are even less clear now that endoscopic treatment is so effective. Accordingly, good cooperation among intensivists, gastroenterologists and surgeons is essential. Indications for surgery can be:

- arterial bleeding that cannot be controlled by endoscopic haemostasis
- massive transfusion (i.e. total of 6–8 units of blood) required to maintain blood pressure
- recurrent clinical bleeding after initial success in endoscopic haemostasis
- evidence suggestive of GI perforation.

Surgical procedures include underrunning of the ulcer, underrunning plus vagotomy and drainage, and various types of gastrectomy. The overall mortality of emergency surgery for GI bleeding is about 15–20%. In a study investigating the best salvage treatment for patients with recurrent bleeding after endoscopic therapy, surgery was found to be comparable to repeating endoscopic treatment in securing haemostasis.[14] However, morbidity is significantly higher in surgical patients than in endoscopic patients. Early surgery should be considered in patients with hypovolaemic shock and/or large peptic ulcer with protuberant vessels. A protocol to manage bleeding peptic ulcer is shown in **Figure 42.1**.[15]

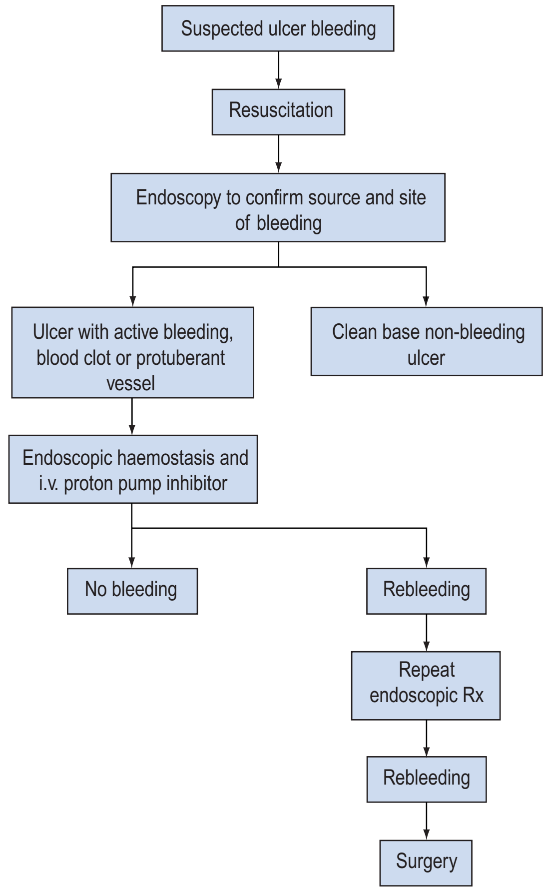

Figure 42.1 Management of peptic ulcer bleeding.

ACUTE STRESS ULCERATION

Acute stress ulceration is associated with shock, sepsis, burns, multiple trauma, head injuries, spinal injuries and respiratory, renal and hepatic failure. Bleeding may be occult or overt, from 'coffee-grounds' aspirates to frank haemorrhage. Lesions are most commonly seen in the gastric fundus, and range from mild erosions to acute ulcerations. The exact mechanism leading to acute mucosal erosion/ulceration in critically ill patients is still unclear. Hypoxia and hypoperfusion of the gastroduodenal mucosa are probably the most important factors, but haemodynamic instability, respiratory failure and coagulopathy are also strong independent factors in critically ill patients. The reported incidence of stress-related mucosal bleeding in ICU patients ranges from 8 to 45%.[16] It has been declining in the last decade as a result of highly effective management of hypotension and hypoxaemia.

PROPHYLAXIS AND TREATMENT

Significant ulcerations are managed as above. Minor bleeding and prophylactic treatment are considered together. Prophylactic treatment aims for gastric alkalinisation (gastric pH > 3.5), with the rationale that gastric acidity is the main cause of stress ulceration.[16] The incidence of stress ulceration appears to be lower with prophylactic gastric alkalinisation than with placebos, although an improvement in survival has not been shown.[17,18] Concerns have included gastric bacterial overgrowth and associated nosocomial pneumonia, but these have not been substantiated by existing data. On balance, prophylactic treatment should probably be reserved only for at-risk patients. The mainstay of prophylaxis and treatment for minor bleeding remains supportive – optimise oxygenation and tissue perfusion and control of infection. There is little consensus among critical care experts in the choice of prophylactic treatment used.[19,20] Drugs given include the following:

Antacids

Antacids given hourly via a nasogastric tube can maintain gastric alkalinisation. Gastric pH monitoring is necessary. Antacids contain magnesium, aluminium, calcium or sodium, and complications may arise from excessive intake of these minerals. Bowel stasis and diarrhoea can also be problems. They are used less commonly now.

Sucralfate

This is a basic aluminium salt of sucrose octasulphate. It is effective in healing ulcers by increasing mucus secretion, mucosal blood flow and local prostaglandin production. These effects promote mucosal resistance against acid and pepsin (i.e. they are cytoprotective). As it does not alter gastric pH, Gram-negative bacterial colonisation of gastric juice is less likely. The incidence of nosocomial pneumonia may be less with sucralfate than with antacids or H_2-receptor antagonists, but this is debatable and is offset by the potential risk of aspiration.[17] Sucralfate is given via a nasogastric tube as 1.0 g every 4–6 hours. Constipation is a side-effect, and aluminium toxicity may arise from renal dysfunction.

H_2-receptor antagonists

These drugs suppress acid secretion by competing for the histamine receptor on the parietal cell. Cimetidine is less potent and has interactions with anticonvulsants, theophyllines and warfarin. Famotidine and nizatidine are newer agents but have no particular advantage over ranitidine. The problem of H_2-receptor antagonists is the development of tachyphylaxis after the first day of administration, leading to reduction of effectiveness in acid suppression. At least one meta-analysis suggested that ranitidine did not confer any protection against stress ulcer in intensive care patients.[21]

Proton pump inhibitors

These are potent acid-suppressing agents as they block the final common pathway of acid secretion by the parietal cell, namely the proton pump. All proton pump inhibitors (omeprazole, lansoprazole, pantoprazole and rabeprazole) can be given as oral medications. Omeprazole and pantoprazole are also available in intravenous form for those who cannot be fed orally. In two non-randomised studies, intravenous omeprazole was shown to protect critically ill patients requiring ventilation from the development of stress-related mucosal bleeding from the upper GI tract.[20] As yet, there are no prospective data indicating which are the high-risk patients who might benefit from this treatment.

VARICEAL BLEEDING

Acute variceal bleeding is a serious complication of portal hypertension, with a high mortality. About 50% of patients with bleeding varices have had an earlier bleed during hospitalisation. The degree of liver failure, using Child–Pugh's classification (see Ch. 44), is the most important prognostic factor for early rebleeding and survival.

RESUSCITATION

Immediate resuscitation with whole blood and fluid is mandatory. Overtransfusion may cause a rebound increase in portal pressure (with a consequent increased risk of rebleeding) and must be avoided. Fresh frozen plasma and platelet concentrates transfusion may be indicated. A nasogastric cannula is often inserted for the removal of blood (and also drug administration). Forceful aspiration through the nasogastric tube should be discouraged as bleeding may be induced. Lactulose (15–30 mL every 4–6 hours) should be given to prevent or correct hepatic encephalopathy. A colonic wash-out can be used, but a magnesium-containing enema should be avoided in the presence of renal failure. Close attention must be given to haemodynamic monitoring.

When the patient is haemodynamically stable, upper GI endoscopy should be performed to identify the source of bleeding. Patients with portal hypertension could bleed from oesophageal or gastric varices, peptic ulcers or portal hypertensive gastropathy or combinations of these.

PHARMACOLOGICAL CONTROL

Vasopressin (0.2–0.4 U/min) used to be the most widely used agent to reduce portal blood pressure and control variceal bleeding. Adverse effects of vasopressin such as cardiac ischaemia (in about 10% of patients) and worsening coagulopathy (by release of plasminogen activator) have discouraged the use of this drug in recent years. Terlipressin, a triglycyl synthetic analogue of vasopressin, has a longer half-life and fewer cardiac side-effects and appears more effective and safe when used in combination with glyceryl trinitrate.[22] Infusion of somatostatin and its analogue (octreotide, vapreotide) reduces portal blood pressure and azygous blood flow. They are safe and effective vasoactive agents to

be used in acute variceal bleeding.[23] The benefit is more pronounced if these vasoactive agents are given early, even before endoscopy.[22,24] Octreotide has also been shown to be effective when used as an adjuvant therapy in combination with endoscopic therapy.[25] Recurrent bleeding episodes and hence requirement of transfusion are significantly reduced. Activated factor VII has recently been tested for control of variceal bleeding. Despite its initial promise in correcting coagulopathy, this drug has not been found effective in controlling variceal bleeding.[26]

ENDOSCOPIC SCLEROTHERAPY

Endoscopic injection sclerotherapy is the mainstay of treatment. At endoscopy, sclerosants can be injected directly into the variceal columns (intravariceal injection) or into the mucosa adjacent to the varices (paravariceal injection) to cause venous thrombosis and inflammation, and tissue fibrosis. Commonly used sclerosants are ethanolamine oleate, sodium tetradecyl sulphate (1–3%), polidocanol and ethyl alcohol. None has appreciable advantage over the others and the choice is very much a personal preference of the endoscopist, and depends also on availability. Endoscopic sclerotherapy controls 80–90% of acute variceal bleeding. Complications such as ulcer formation, fever, chest pain and mediastinitis are common. Bleeding from gastric varices is more difficult to control by injection sclerotherapy because of difficult access.

Butylcyanoacrylate (Histoacryl®) has recently been used for gastric variceal injections, with a claimed superior haemostatic effect. It is mixed with lipiodol to delay the rate of polymerisation and allow radiological monitoring of the injection.

ENDOSCOPIC VARICEAL LIGATION

Endoscopic variceal ligation was introduced in the late 1980s as a mechanical method to control bleeding from varices. Rubber bands mounted on the banding device at the tip of the endoscope are released to strangulate the bleeding varices. Numerous studies comparing endoscopic variceal ligation with endoscopic sclerotherapy showed that the technique is as effective as injection sclerotherapy in acute bleeding. Procedure-related complications are significantly fewer, as there is no tissue chemical irritation. An overtube to facilitate banding avoids aspiration during the procedure, but may result in serious oesophageal injury if used improperly. The tunnel vision produced by the banding device as originally designed restricts visibility, and thus makes the procedure technically difficult when bleeding is heavy. With the introduction of multiple banding devices that are loaded with 5–10 rubber bands, and the use of transparent caps, the problems of overtube injury and tunnel vision have been overcome. In many centres, endoscopic variceal ligation has replaced injection sclerotherapy as the first choice for variceal haemorrhage. Many have combined the two endoscopic treatments together in an attempt to improve the outcome. Existing data so far do not suggest this combined therapy is any better, however, hence combined endoscopic therapy cannot be recommended.

BALLOON TAMPONADE

Variceal bleeding can be controlled by exerting pressure directly on the bleeding point using a balloon. The Sengstaken–Blackmore tube has been replaced by the four-lumen Minnesota tube, which allows aspiration of gastric and oesophageal contents. Inflation of the gastric balloon (by 250–350 mL of water) is often sufficient to stop the bleeding by occluding the feeding veins to the oesophageal varices. If bleeding continues, the oesophageal balloon can be inflated by air and kept at a pressure of 50–60 mmHg (6.7–8.0 kPa). Duration of using balloon tamponade should be limited to 24 hours to avoid tissue pressure necrosis. Because of available effective pharmacological and endoscopic therapies, balloon tamponade should be used only in the exceptional cases when these therapies fail to effect control of bleeding.

TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT (TIPS)

Using a transjugular approach, a catheter is inserted into the hepatic vein, and advanced under fluoroscopic guidance into a branch of the portal vein.[27] By means of a guidewire and dilators, a self-expandable metal stent is introduced to create an intrahepatic portosystemic shunt. In good hands, success can be achieved in over 90% of cases. This procedure significantly reduces portal blood pressure and thus bleeding from varices. Major complications include intra-abdominal haemorrhage and stent occlusion. Hepatic encephalopathy has been reported in 25–60% of patients. Nevertheless, this is an effective salvage treatment for uncontrolled variceal bleeding. Meta-analysis comparing TIPS with endoscopic therapy showed that the former has secure haemostasis but at the cost of increasing risk of hepatic encephalopathy.[28]

A number of markers of outcome after TIPS have been under investigation, including the Acute Physiology, Age and Chronic Health Evaluation (APACHE) score, presence of hyponatraemia and Child C liver disease, hepatic encephalopathy before TIPS, presence of ascites and serum albumin. Until a reliable marker of outcome can be identified, TIPS should be reserved for the subset of patients who continue to bleed or develop recurrent bleeding after endoscopic therapy. Unlike shunt surgery, TIPS will not reduce the chance of future liver transplantation.

SURGERY

Surgical treatments for variceal bleeding include direct devascularisation of the lower oesophagus plus the proximal stomach and a variety of surgical shunts. The role of surgery has diminished since the advent of endoscopic treatment and TIPS.[29] Surgery is now used

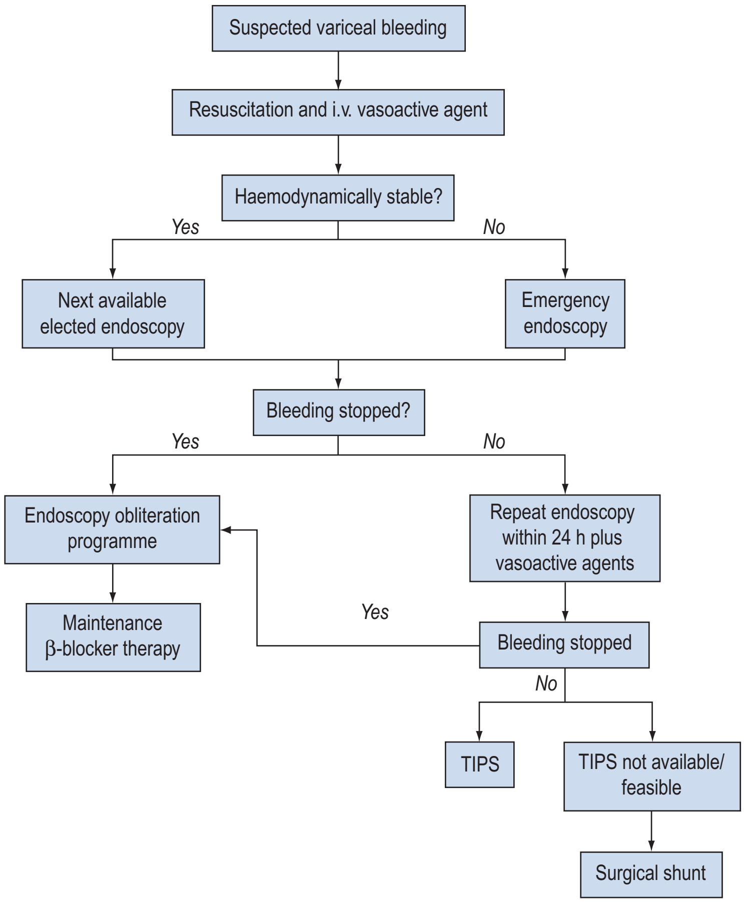

Figure 42.2 Management of variceal haemorrhage. TIPS=transjugular intrahepatic portosystemic shunt.

as a second-line treatment, when bleeding continues or recurs after two sessions of injection sclerotherapy or banding ligation. Both staple transection of the oesophagus and portocaval shunt surgery are highly effective emergency measures. Despite successful control of bleeding, long-term survival is not significantly improved. Hepatic encephalopathy is one of the major complications of shunting operations. Expectations that the Warren distal splenorenal shunt will preserve antegrade portal flow and avoid accelerated deterioration of liver function have not been realised. The Warren shunt is technically more difficult, especially if performed as an emergency. Choice of surgery should be carefully made in those who are potential transplant candidates, as it may complicate subsequent surgery. A protocol to manage variceal bleeding is shown in **Figure 42.2**.

LOWER GASTROINTESTINAL BLEEDING

Lower GI bleeding arises from a source distal to the ligament of Treitz. It accounts for 10–20% of acute GI bleeding. Common causes of colonic bleeding include diverticular haemorrhage and angiodysplasia (both occur on the right-sided colon), colonic polyps and carcinoma, and inflammatory bowel diseases.

CLINICAL PRESENTATION

Haematochezia (bright-red blood) is the most common presentation of lower GI bleeding. However, bleeding from small intestine and right colon may also present as melaena. Abdominal pain preceding a massive bleeding episode suggests either ischaemia or inflammatory bowel disease. Painless massive bleeding is common in diverticulosis, angiodysplasia or from a Meckel's diverticulum. In a patient with portal hypertension, haemorrhoids may present with massive haematochezia.

INVESTIGATIONS

Haemorrhoids and rectal tumour can easily be identified by proctosigmoidoscopy, which should always be performed. Since upper GI bleeding is about five times as common as lower GI bleeding, the former should be excluded. When both proctosigmoidoscopy and gastroscopy are negative, the lower GI tract should be

examined by colonoscopy, angiography or radionucleotide scan. Barium enema plays no role in the management of acute rectal bleeding.

COLONOSCOPY

Patients with mild-to-moderate haematochezia can be examined safely by colonoscopy. Colonoscopy is difficult in an actively bleeding patient, and may carry an increased risk of perforation. Visualisation is often unsatisfactory due to the dark discoloration of blood. Colonoscopy yields much better results with adequate bowel preparation once bleeding has stopped. Therefore as a technique urgent/emergency colonoscopy does not seem to be necessary as it will not improve the outcome of patients with lower gastrointestinal bleeding.[30]

ANGIOGRAPHY OR RADIONUCLIDE SCAN

The diagnostic efficacy of radionuclide scan and angiography varies in different studies. ^{99m}Tc sulphur colloid is quickly removed from the bloodstream after injection. Its diagnostic yield is low because of its short circulatory half-life. ^{99m}Tc labelling of red cells prolongs the duration of radioactivity in the body. Red cell scan has been reported to detect the source of active bleeding in over 80% of cases.

Diagnostic angiography is helpful in two situations: (1) when the view of endoscopy is completely obscured by active haemorrhage; (2) in defining abnormal vasculatures, where angiography is more sensitive even if extravasation of contrast material is not seen. These lesions include angiodysplasia, arteriovenous malformation and various inherited vascular anomalies (e.g. Rendu–Osler–Weber syndrome, pseudoxanthoma elasticum and Ehlers–Danlos syndrome). Angiography may localise the site of bleeding in 80–85% of patients when the bleeding rate is more than 0.5 mL/min. Both superior and inferior mesenteric angiograms are often needed.

MANAGEMENT

ENDOSCOPY

Bleeding from vascular anomalies can be treated by electrocoagulation, heater probe and laser photocoagulation, unless the anomalies are too large or too diffuse. Bleeding colonic polyps can be removed by polypectomy or coagulated by hot biopsy forceps. Bleeding

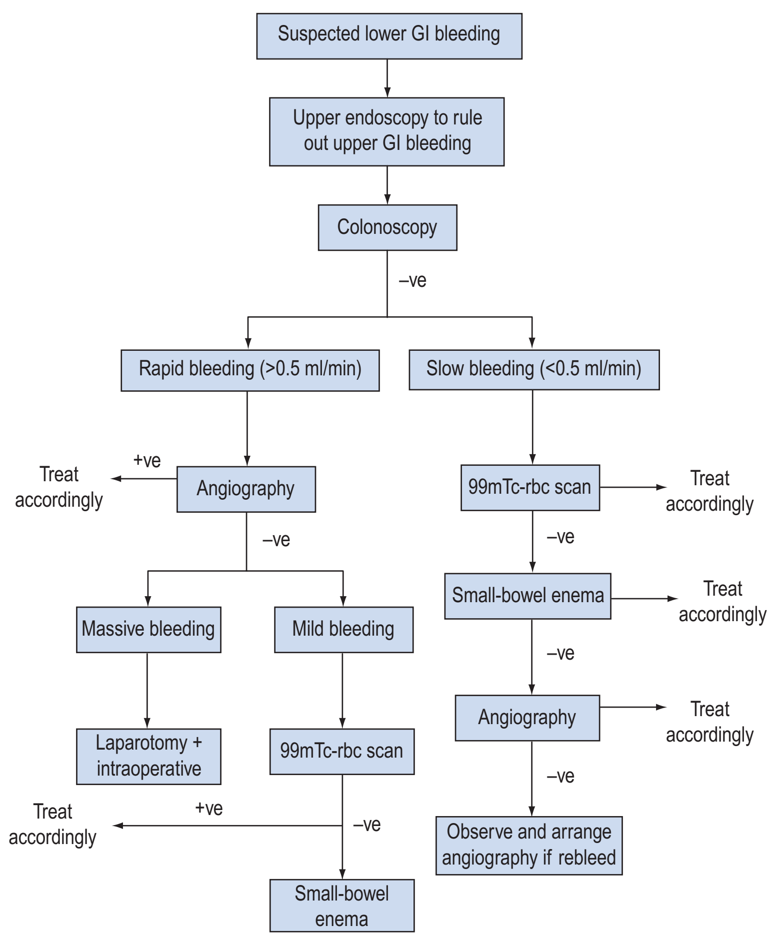

Figure 42.3 Management of lower gastrointestinal (GI) bleeding.

from colonic diverticula can also be controlled with thermocoagulation through colonoscopy.[31]

ANGIOGRAPHY

Angiographic intra-arterial infusion of vasopressin or occlusion of the bleeding artery with embolic agents such as an absorbable gelatin sponge (Gelfoam®) may be used in lower GI bleeding pathologies. Both diverticular bleeding and bleeding from angiodysplasia can be stopped by vasopressin infusion during angiography, but recurrence of bleeding frequently occurs with diverticular disease.

SURGERY

Diverticular bleeding usually arises from a relatively large vessel, and may be difficult to control with endoscopic or angiographic therapy. Partial resection of the colon is warranted after localisation of the bleeding site. Surgery is also indicated in vascular anomalies when endoscopic treatment fails. When an obvious and refractory massive lower GI bleeding is not identified by endoscopic or angiographic examinations, immediate laparotomy with possible subtotal colectomy should be offered. A protocol to manage lower GI bleeding is shown in **Figure 42.3**.

Severe acute pancreatitis

Duncan LA Wyncoll

Acute inflammation of the pancreas produces a spectrum of symptoms, which may be mild and self-limiting, or reflect severe disease that rapidly leads to multiple-organ failure and death. In a majority of patients a treatable underlying cause is identified. Although mild, interstitial, oedematous pancreatitis is more common, it is the more severe form – acute necrotising pancreatitis (ANP) – that accounts for the associated mortality. Two decades ago the mortality was frequently quoted to be 25–35%, even in the best centres.[1] However, more recently published series have suggested a lower mortality (15%).[2] Management of patients with severe ANP is time consuming, and labour and resource intensive. Long-term follow-up suggests that, although some survivors suffer permanent exocrine and endocrine insufficiency, most maintain a good quality of life.[3]

In the last 20 years there has been a gradual move towards aggressive supportive therapy for ANP. Numerous putative therapeutic interventions have been tried, but few have provided any objective evidence of clinical benefit.

AETIOLOGY

Biliary disease and alcohol remain the two commonest causes of acute pancreatitis worldwide, accounting for about 70% of cases. Although no discernible cause is found in many of the remaining cases, there are well-established associations with a number of infections, certain drugs, hyperlipidaemias and trauma. See **Box 43.1** for a more exhaustive list.

RANSON'S CRITERIA

Although the overall mortality rate for acute pancreatitis is approximately 5–10%, the vast majority of deaths occur in those with the severe form of the disease. Since 1974 the standard means of documenting the severity of disease and risk of mortality has been by Ranson's criteria (**Box 43.2**).[4] These factors were determined following the analysis of just 100 patients with predominantly alcohol-induced pancreatitis using clinical and laboratory data obtained at admission and after 48 hours, and the number of positive criteria should predict outcome. A decade later these criteria were re-evaluated and the first eight were found to be most predictive – this is now known as the Glasgow criteria, or Imrie score.[5]

SCORING

The Acute Physiology and Chronic Health Evaluation (APACHE) II scoring system has also been used in predicting the severity of pancreatitis, and can be used daily throughout the patient's hospital admission rather than solely within the first 48 hours, thus potentially documenting progress or deterioration. However, such scoring systems are complex to perform and have been evaluated only prospectively 24–48 hours after the onset of pancreatitis, which means that the criteria may not be valid for patients subsequently admitted to the intensive care unit (ICU). Those factors with most predictive value for mortality include advanced age, presence of renal or respiratory insufficiency and presence of shock.

The scoring of patients with acute pancreatitis is important for a number of reasons. Firstly, the clinician can be alerted early to the presence of potentially severe disease. Secondly, comparisons of severity can be made both within and between patient series; and thirdly, rational selection of patients can be made for inclusion in trials of potential new treatments or interventions. Unfortunately the scoring systems used at present are often inadequate in patients with severe ANP, which is sometimes characterised by rapidly progressive multiple-system organ dysfunction. In this setting the Ranson criteria and APACHE score do not take account of the effects of treatment upon measured parameters. The solution may be to use a combination of the Ranson score, the radiological scoring systems (see below) and a descriptive organ failure score such as the Sepsis-related Organ Failure Assessment.[6]

THE MANAGEMENT OF SEVERE PANCREATITIS

IMAGING

Dynamic contrast-enhanced computed tomography (CT) provides the best means of accurately visualising the pancreas and diagnosing pancreatitis and its local complications. It may also be used for guiding percutaneous catheter drainage.

Box 43.1 Aetiology of acute pancreatitis

Excess alcohol ingestion
Biliary tract disease
Idiopathic
Metabolic
Hyperlipidaemia
Hyperparathyroidism
Diabetic ketoacidosis
End-stage renal failure
Pregnancy
Post renal transplant
Mechanical disorders
Posttraumatic, postoperative, post endoscopic retrograde cholangiopancreatography
Penetrating duodenal ulcer
Duodenal obstruction
Infections
Human immunodeficiency virus, mumps, Epstein–Barr virus, *Mycoplasma, Legionella, Campylobacter*, ascariasis
Vascular
Necrotising vasculitis – systemic lupus erythematosus, thrombotic thrombocytopenia
Atheroma
Shock
Drugs
Azathioprine, thiazides, furosemide, tetracyclines, oestrogens, valproic acid, metronidazole, pentamidine, nitrofurantoin, erythromycin, methyldopa, ranitidine
Toxins
Scorpion venom, organophosphates, methyl alcohol

Box 43.2 Adverse prognostic factors in acute pancreatitis
Ranson's score[4]

On admission
Age >55 years
White cell count >16 000/mm^3
Glucose 11 mmol/L
Lactate dehydrogenase 400 IU/L
Aspartate transaminase >250 IU/L
Within 48 hours of hospitalisation
Decrease in haematocrit >10%
Increase in blood urea >1.8 mmol/L
Calcium <2 mmol/L
Pa_{O_2} <8 kPa
Base deficit >4 mmol/L
Fluid deficit >6 L

Risk factors	Mortality rate
0–2	<1%
3–4	≅15%
5–6	≅40%
>6	≅100%

Blamey et al.[5] found that only eight variables (not lactate dehydrogenase, base deficit and fluid deficit) were predictive and are often referred to as the Glasgow criteria or Imrie score.

In severe acute pancreatitis, there is lack of normal enhancement to contrast of all or part of the gland. This is consistent with pancreatic necrosis, defined as diffuse or focal areas of non-viable parenchyma. Microscopically, there is evidence of damage to the parenchymal network, acinar cells and pancreatic ductal system and necrosis of perilobular fat. Areas of necrosis are often multifocal, rarely involving the whole gland, and may be confined to the periphery with preservation of the core. Necrosis develops early in the course of the disease and is usually established 96 hours after the onset of symptoms. The extent of pancreatic necrosis and the degree of peripancreatic inflammation have been used to determine outcome. A grading system combining the two CT prognostic indicators (the extent of necrosis and the grade of peripancreatic inflammation) gives the 'CT severity index'.[7]

Most complications of acute pancreatitis occur in patients in whom the initial diagnosis is based upon peripancreatic fluid collections, and a strong correlation has been established between the CT depiction of necrosis and the development of complications and death.[8] In patients with necrosis in the pancreatic head, the outcome is as severe as when the entire pancreas is affected. By contrast, for patients with necrosis in only the distal portion of the gland, the outcome is usually good, with few complications. The mechanism may be that necrosis in the pancreatic head causes obstruction of the pancreatic duct, and produces a rise in pressure in the acinar cells leading to damage and leakage of activated destructive proteases.

Following the initial CT scan, repeated scanning is indicated if the patient's clinical condition deteriorates, usually through the development of pancreatic necrosis, abscess or pancreatic pseudocyst, haemorrhage, or colonic ischaemia or perforation.

Ultrasonography in acute pancreatitis is less useful since visualisation of the gland may be obscured by 'gas-filled' bowel. Moreover, the degree of necrosis, which determines prognosis, cannot be assessed. However, there may be a role for this mode of imaging in demonstrating gallstones, or in the subsequent management when ultrasound-guided fine-needle aspiration (FNA) of the pancreas or surrounding tissue may help to establish the presence of infection.

SURGERY IN SEVERE PANCREATITIS

In previous decades the role of surgery was a controversial area in the management of severe ANP. During the 1980s, most patients with acute pancreatitis of even moderate severity underwent operative intervention; this was particularly true for those patients thought to have infected pancreatic necrosis. The results were poor, with mortality rates in excess of 50%, although this was sometimes without ICU support. In the 1990s

the concept of a conservative, non-surgical approach to severe ANP was developed. Targeted surgical intervention according to infection status, based on Gram stain and culture of ultrasound or CT-guided FNA, has refined this conservative approach with significantly better results.[9] The aim now is often to postpone surgery for as long as possible. Many centres report that a conservative approach and avoiding open necrosectomy result in lower mortality. Open surgery is reserved for concomitant intra-abdominal complications.

If severe acute pancreatitis is an unsuspected 'chance' finding at laparotomy, a T-tube should be inserted into the common bile duct, particularly if it has been explored and the opportunity taken for placement of a feeding jejunostomy tube. Some surgeons oppose this approach, as opening a hollow viscus risks peritonitis.

PANCREATIC ABSCESSES

Pancreatic abscesses are circumscribed collections of pus containing little or no pancreatic necrosis, which arise as a later consequence of severe acute pancreatitis or pancreatic trauma. They commonly occur about 3–4 weeks after the onset of severe pancreatitis, and a CT scan most accurately makes the diagnosis. If the appropriate expertise is available, percutaneous catheter drainage may be very successful. Some series report effective drainage of intra-abdominal collections with a single treatment in 70% of patients, increasing to 82% with a second attempt, although proceeding to open surgical drainage is more frequently required in pancreatic abscess, especially if complicated by yeast infection.[10]

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY (ERCP)

ERCP represents an alternative approach, particularly for patients with severe biliary pancreatitis. A number of prospective randomised studies have been carried out to compare early ERCP with conservative treatment in acute biliary pancreatitis. Although the studies are not entirely consistent, ERCP and papillotomy seem to be beneficial in confirmed or suspected severe biliary pancreatitis if undertaken by a skilled operator, whereas in mild pancreatitis the risks of intervention probably outweigh the benefits. This observation is confirmed by both a systematic review of the five ERCP trials[11] and by the recommendations of the 2004 International Consensus Conference on the management of severe acute pancreatitis in the critically ill.[12]

TREATMENT WITH PHARMACOLOGICAL AGENTS

Theories regarding the pathogenesis of acute pancreatitis have promoted the concept that autodigestion of the gland and peripancreatic tissue by activated pancreatic enzymes is a central component. This has led to the suggestion that the reduction of pancreatic exocrine secretion, thereby 'resting the pancreas', might improve outcome. The problem is that the secretory status of the pancreas in severe ANP is not known. Consequently, it is not clear whether inhibition of secretion actually occurs or whether this is beneficial. Therapies designed to inhibit pancreatic secretion, such as H_2-blockers, atropine, calcitonin, glucagon and fluorouracil, do not alter the course of the disease. However, other pharmacological therapies, such as aprotonin and gabexate mesilate, both protease inhibitors, and somatostatin and octreotide, are still in widespread use in the hope of improving the outcome.

SOMATOSTATIN AND OCTREOTIDE

Somatostatin and its long-acting analogue octreotide are potent inhibitors of pancreatic secretion. They also stimulate activity of the reticuloendothelial system and play a regulatory role, mostly inhibitory, in the modulation of the immune response via autocrine and neuroendocrine pathways. Both are cytoprotective with respect to the pancreas.[13] Other effects include:

- Somatostatin also blocks the release of tumour necrosis factor and interferon-γ by peripheral mononuclear cells.
- Octreotide increases the phagocytotic activity of monocytes.

These actions may be important in the modulation of the pathogenesis of acute respiratory distress syndrome (ARDS) and septic shock, both of which can complicate severe ANP. Both agents are effective in experimental pancreatitis, and in the prevention of complications in patients undergoing surgery for chronic pancreatitis, but potential difficulties include:

- Pre-emptive administration is not possible in the acute situation.
- Both agents are powerful splanchnic vasoconstrictors.
- The development of pancreatic necrosis has been linked to hypoperfusion of the gland and vasoconstrictors worsen the histological severity of experimental pancreatitis.[14]

Consequently, these agents have both beneficial and detrimental effects. Systematic evaluation suggests that there is insufficient evidence to support the use of octreotide or somatostatin in the treatment of patients with moderate to severe acute pancreatitis.[15] Additionally, the therapeutic effect of octreotide, if present at all, is probably very small and therefore unlikely to have any significant impact on the management of ANP.

PROTEASE INHIBITORS

A further pathogenic mechanism involved in acute pancreatitis is autodigestion of the pancreas by the activation of proteases. More accurately, there is an imbalance between proteases and antiproteases. Aprotinin and gabexate mesilate are proteolytic enzyme inhibitors that act on serine proteases such as trypsin,

phospholipase A_2, kallikrein, plasmin, thrombin and C1r and C1s esterases.

Numerous studies of the protease inhibitor gabexate mesilate in patients with variable severity of pancreatitis have now been undertaken. Taken together these show no significant reduction in mortality, length of stay or the need for surgery.[16]

The reason why these agents, in clinical practice, do not have the expected beneficial effect on outcome may be the lag time between the onset of pancreatitis and administration. Additionally, derangement to the microvascular control of the pancreas combined with increased vascular permeability may contribute. Continuous regional arterial infusion or intraperitoneal administration may be more advantageous, but so far trials using these modes of administration have only involved small numbers of patients. At present, there is insufficient evidence to recommend protease inhibitors in ANP.

ANTI-INFLAMMATORY THERAPY

Patients with ANP exhibit a generalised uncontrolled inflammatory response. Potentially there is a therapeutic window between the onset of symptoms and the development of organ failure during which anti-inflammatory therapy might be successful. Potential targets include tumour necrosis factor-α, interleukin (IL)-1β, IL-6, IL-8, IL-10, platelet-activating factor and intracellular adhesion molecules.[17] Although many have been studied in animals, there are limited human data.

It is also fascinating to observe that there is a constellation of changes in hypopituitary–adrenal axis hormone levels that strongly suggests that the existence of relative adrenocortical insufficiency in patients with ANP is very comparable to that of severe sepsis and multiple-organ failure.[18] There are currently no published trials of corticosteroid therapy in patients with ANP.

PROPHYLACTIC ANTIBIOTICS

Bacterial infection of necrotic pancreatic tissue occurs in approximately 50% of patients with ANP, and infection is the major cause of morbidity and mortality. Early studies investigating the role of prophylactic antibiotics in acute pancreatitis showed no benefit, but most included patients with mild disease and employed agents (e.g. ampicillin) with inefficient penetration of pancreatic tissue. Subsequent studies have still not clarified their role, and prophylactic use remains widespread but controversial.

Carbapenems have exceptional penetration into pancreatic tissues and broad activity against most of the common pathogens encountered in this disease. In the 1990s there was hope that this new class of antibiotic would prove more useful; and some of the early trials did suggest a modest benefit with imipenem.[19] The incidence of septic complications was significantly reduced in the treated group (12.2 versus 30.3%), although there was only a trend towards decreased mortality (7 versus 12%). However, the most recent systematic review, which included 14 trials (but still only 841 patients), suggested antibiotic prophylaxis was not associated with a statistically significant reduction in mortality (RR 0.74 [95% CI 0.50–1.07]), in the incidence of infected pancreatic necrosis (RR 0.78 [95% CI 0.60–1.02]) or in the incidence of non-pancreatic infections (RR 0.70 [95% CI 0.46–1.06]).[20] Of note though, in the majority of these trials, patients with severe ANP and overt shock *were excluded*, leaving open the possibility that prophylactic antibiotics may still have a role in the very sickest patients.

Patients with mild pancreatitis definitely do not benefit from antibiotics.

PROPHYLACTIC ANTIFUNGAL THERAPY

The incidence of fungal infection correlates with the extent of pancreatic necrosis, as well as the severity of disease on admission. Antibiotic administration has been claimed to promote fungal infection; however, up to 25% of patients with ANP who do not receive antibiotics also develop fungal infection with an associated mortality rate of up to 84%.[21] One small, randomised study suggested fluconazole reduced the rate of fungal infection, but had no effect on mortality. Advocates of prophylactic antifungal therapy argue that it may delay the need for surgery, which is associated with a better outcome.[22]

SELECTIVE DECONTAMINATION OF THE GUT

The original selective digestive decontamination (SDD) strategy contained three components: oropharyngeal and gastric decontamination with polymyxin E, tobramycin, and amphotericin B and intravenous cefotaxime for 4 days.[23] There is ongoing debate as to the effectiveness of this strategy and results are conflicting regarding any reduction in mortality, particularly when applied to a general critically ill population. However, more promising results have been seen in specific patient populations.

Severe acute pancreatitis may be one clinical situation that supports the hypothesis that gut hypoperfusion promotes bacterial translocation, leading to infection of the inflamed pancreas and peripancreatic tissue.[24] The only controlled trial of SDD in pancreatitis was performed in 102 patients[25] who were randomised to receive SDD: oral colistin, amphotericin and norfloxacin with addition of a daily dose of the three drugs given as a rectal enema and systemic cefotaxime until Gram-negative bacteria were successfully eliminated from the oral cavity and rectum. Surveillance samples were taken regularly to assess whether any subsequent infection was of exogenous or endogenous origin. There were 18 deaths (35%) in the control group, compared with 11 (22%) in the SDD group ($P < 0.05$). This difference was caused by a fall in late mortality due to significant reduction in the incidence of Gram-negative pancreatic infection. There was also a reduction in the

mean number of laparotomies in the SDD patients. Since the SDD regimen used in this study incorporated intravenous cefotaxime it could be argued that the improvement in outcome was not due to the colistin, amphotericin or norfloxacin components, but merely due to a systemic antibiotic effect.

Meta-analyses and even large randomised controlled trials of this intervention continue to suggest clear trends towards a reduction in mortality in critically ill patients.[26] However, the perhaps unfounded fear of the emergence of resistant Gram-positive cocci prevents widespread adoption of this strategy.

NUTRITIONAL SUPPORT IN ACUTE NECROTISING PANCREATITIS

The provision of nutritional support for the patient with ANP is an essential component of supportive therapy, especially since many patients with pancreatitis are nutritionally depleted prior to their illness and face increased metabolic demands throughout the course of their disorder. Failure to reverse or prevent malnutrition, and a prolonged negative nitrogen balance, increases mortality rates. The route by which nutrition is administered is, none the less, still debated. In the last two decades there has been a trend away from the use of total parenteral nutrition (TPN) in favour of enteral nutrition (EN) in supporting the critically ill. Studies suggest that TPN started within 24 hours of admission to ICU, compared with a watch-and-wait policy and/or EN where tolerated is associated with increased infective complications and hospital length of stay.[27]

TOTAL PARENTERAL NUTRITION

Severe pancreatitis is still sometimes stated as an absolute contraindication to EN, and TPN is considered by some as 'standard' therapy by some physicians. This is largely because it is regarded as a way of 'resting the pancreas', based on the assumption that the necrotic pancreas is still a secretor of activated enzymes. In fact, the secretory state of the pancreas has never been prospectively studied in severe necrosis. Several retrospective and prospective evaluations of TPN in acute pancreatitis have failed to demonstrate conclusively an effect on survival, or on the incidence and severity of organ failure.

ENTERAL NUTRITION

An increasing number of reports on the use of EN in severe ANP confirm that it is safe and feasible for not all but the majority of patients. When EN is given it has been suggested that it should be delivered distal to the ligament of Treitz, below the area of the cholecystokinin (CCK) cells distal to the third part of the duodenum, as CCK stimulation may worsen the course of the disease. Intragastric delivery of nutrients may result in an increased volume of pancreatic protein and bicarbonate secretion. By contrast, jejunal nutrient delivery does not appear to increase pancreatic exocrine secretion.

Consequently, jejunal tube feeding as far distally as possible in the upper gastrointestinal tract conforms to the concept of 'pancreatic rest'. A number of comparisons of EN with TPN have been made in mild and severe acute pancreatitis, all suggesting that EN is well tolerated without adverse effects on the course of the disease.[28] Patients who received EN experienced fewer total complications and were at lower risk of developing septic complications than those receiving TPN.[29] EN seems to modulate the inflammatory and sepsis response beneficially, and if tolerated may be superior to TPN. In spite of the enthusiasm for EN of some clinicians, in ANP, where there is often an ileus and slow bowel transit time, some patients will not tolerate it. It is not uncommon to be faced with the option of no nutrition or TPN; in this situation TPN with normoglycaemic control should be used.

An international task force has recently made some recommendations,[30] which can be summarised as follows:

1. Most patients with mild or moderate uncomplicated pancreatitis do not benefit from nutritional support.
2. In moderate to severe pancreatitis, let hyperacute inflammation settle, then start a trial of EN via a jejunal tube.
3. In patients who require surgery for diagnosis or treatment, a jejunal tube should be placed, either pulled down from the stomach, or a separate jejunostomy.
4. TPN is indicated only if a 5–7-day trial of EN is not tolerated.
5. In all patients, whether fed enterally or parenterally, a protocol ensuring good glycaemic control is recommended.

CONCLUSION

The main determinant of outcome in severe acute pancreatitis is the extent of pancreatic necrosis and the subsequent risk for the development of infected necrosis. A thorough assessment using appropriate scoring systems and the early use of dynamic contrast-enhanced CT will highlight those patients likely to benefit from early critical care. Despite numerous suggested specific therapies there is still no incontrovertible evidence that any one confers a significant mortality benefit. However, general supportive measures should include vigorous replacement of fluid losses to correct circulating volume, correction of electrolyte and glucose abnormalities, and respiratory, cardiovascular and renal support as necessary. Patients with sterile necrosis should receive a broad-spectrum prophylactic antibiotic that adequately penetrates pancreatic tissue if they develop shock. Due attention should also be paid to nutritional support, for which a jejunal feeding tube with EN is recommended prior to initiation of TPN.

Liver failure

Christopher Willars and Julia Wendon

44.1 Acute hepatic failure

DEFINITIONS

The manner in which acute deteriorations in hepatic function are described is not uniform. In this chapter, we use the term *acute hepatic failure* to describe both *acute liver failure* (ALF) and *acute on chronic liver failure* (ACLF) – which are distinct clinical entities and which require very different management strategies.

ACUTE LIVER FAILURE

Acute liver failure (ALF) is a rare condition, with about 400 cases per year in the UK. ALF arises in the context of massive parenchymal injury and results in a multisystem disorder that is phenotypically similar to severe septic shock. Liver damage is manifest by coagulopathy and encephalopathy, which occurs within days or weeks of the liver injury. There is diversity in terms of aetiology and in terms of clinical progression.

Patients with ALF may initially appear relatively well, but progression to multi-organ failure is rapid. The key to a successful outcome lies in prompt recognition, resuscitation and referral to a specialist centre.

CLASSIFICATION

The clinical classification described by O'Grady et al[1] (**Table 44.1.1**) uses the time from jaundice to encephalopathy to differentiate between hyperacute, acute and subacute liver failure. It is particularly useful because it informs us of likely aetiology and clinical course.

Hyperacute liver failure progresses rapidly (the onset of encephalopathy is within 7 days of the development of jaundice) and is generally associated with profound coagulopathy, high-grade encephalopathy, severe organ dysfunction and a higher incidence of intracranial hypertension, but confers higher rates of spontaneous survival. The onset of encephalopathy often precedes clinical jaundice.

Acute liver failure has an intermediate course. Common aetiologies include the viral hepatitides and idiosyncratic drug reactions.

Subacute liver failure is associated with a later onset of encephalopathy, but with the worst outcomes in the absence of transplantation. Aetiology is frequently seronegative (idiopathic – the history suggests a viral or immune-mediated aetiology but all serological tests are negative) or drug related. Jaundice is inevitable but the transaminitis is often less pronounced than in acute and hyperacute presentations. Patients frequently present with established ascites and so may be clinically difficult to distinguish from those with chronic liver disease (CLD).

AETIOLOGY

Determination of the aetiology of ALF (**Box 44.1.1**) is important for prognostication and because specific therapy may be available. There is a wide geographical variation in the aetiology of ALF. Acetaminophen (paracetamol) toxicity is responsible for the majority of cases of ALF seen in the UK and the USA, whereas viral hepatitis is the most common cause of ALF worldwide (**Table 44.1.2**).

A good history and review of the results of blood tests over the preceding weeks are essential to making a diagnosis. Any new drug ingestion (prescribed, recreational or over the counter) should be considered a potential culprit and discontinued if possible. In addition any treatments that may be detrimental to liver recovery should be avoided.

DIAGNOSIS

A standardised investigative pathway ensures clinical consistency. *Laboratory tests* that may be useful in establishing a diagnosis are listed in **Table 44.1.3**. It is paramount that diagnosis proceeds in tandem with resuscitative measures.

Doppler ultrasound is very useful in determining patency of the hepatic artery, vein and portal vein. Budd–Chiari syndrome, ischaemic hepatitis, portal vein thrombosis and even tricuspid regurgitation may be apparent. *Ultrasound examination* of the liver parenchyma may reveal heterogeneity, fatty infiltration (reflectivity) and tumour. Splenomegaly and ascites are evident, if present.

Axial CT imaging provides additional information about other abdominal anatomy, lymphadenopathy and liver perfusion. Serial imaging in ALF may

Table 44.1.1 Classification of acute liver failure

DEFINITION	TIME (DAYS)	COMMONEST AETIOLOGIES
Hyperacute	<7 days	Acetaminophen overdose, hepatitis A and B
Acute	8–28 days	Hepatitis ABE, idiosyncratic drug reactions
Subacute	29 days–8 weeks	Idiosyncratic drug reaction, seronegative hepatitis

Box 44.1.1 Aetiology of ALF

Viral hepatitis
Hepatitis A, B, D, E, seronegative hepatitis
Herpes simplex, cytomegalovirus, chickenpox – usually limited to immunocompromised hosts
Drug-related
Acetaminophen
Antituberculous drugs
Recreational drugs (ecstasy, cocaine)
Idiosyncratic reactions (anticonvulsants, antibiotics, non-steroidal anti-inflammatory drugs (NSAIDs))
Aspirin in children may lead to Reye syndrome
Kava kava
Toxins
Carbon tetrachloride, phosphorous, *Amanita phalloides*, alcohol
Vascular events
Ischaemia, veno-occlusive disease, Budd–Chiari syndrome (hepatic vein thrombosis)
Hyperthermic liver injury
Pregnancy
Acute fatty liver of pregnancy, HELLP syndrome, liver rupture
Other
Wilson's disease, autoimmune, lymphoma, carcinoma, haemophagocytic syndrome. trauma

demonstrate a collapsing liver (**Fig. 44.1.1**). Nodularity of the liver should not be assumed to represent cirrhosis and chronic liver disease. The imaging pattern of subacute liver failure, with focal areas of collapse and regeneration, may be difficult to distinguish from cirrhosis.

Liver biopsy is rarely undertaken in the acute setting because of the high risk of bleeding. The contribution of histology to the assessment of ALF is controversial. Features suggestive of specific diagnoses such as Wilson's disease (cirrhosis) and autoimmune features may be evident and histology may be particularly useful if infiltration with tumour is suspected and a tissue diagnosis is required prior to consideration of systemic chemotherapy. However, in ALF, non-specific confluent necrosis is the commonest histological finding. Its severity has been used to assess prognosis: >50% necrosis is associated with poor prognosis. However, nodules of regeneration may occur randomly, particularly in subacute liver failure, and sampling error may thus make this a less than ideal tool for predicting outcome. The transjugular route is considered safest, although there is a risk of sampling error.

Table 44.1.2 Geographical distribution of aetiology in ALF

	UK	US	FRANCE	INDIA	JAPAN
Paracetamol	54	40	2	–	–
Drug induced	7	12	15	5	–
Seronegative	17	17	18	24	45
Hepatitis A/B	14	12	49	33	55
Hepatitis E	–	–	–	38	–
Other	8	19	16	–	–

Echocardiography should be performed to exclude low cardiac output states as a cause of hypoxic hepatitis, and where transplantation is considered.

PARACETAMOL (ACETAMINOPHEN) TOXICITY

Paracetamol, taken intentionally or inadvertently, remains one of the commonest forms of acute hepatotoxicity. This incidence of paracetamol overdose has risen since the 1970s and in 1998 the Medicines Control Agency (UK) introduced legislation to limit its availability, and paracetamol is now sold as 16×500 mg tablets; a maximum of 8 g per packet.

Cytochrome P450 enzymes convert ~5% of acetaminophen to *N*-acetyl *p*-benzoquinone imine (NAPQI), a metabolite which is normally detoxified by conjugation with hepatic glutathione. Hepatocellular glutathione becomes rapidly depleted in overdose, and NAPQI persists, causing damage to cell membranes leading to hepatocyte death unless NAC (N-acetylcysteine or methionine is administrated in a timely fashion.

Following massive paracetamol ingestion, relatively small doses are absorbed and when NAC is administered early less than 1% of cases result in significant hepatotoxicity.

The recommended dosage schedule is 150 mg/kg in 5% dextrose over 15–60 minutes, followed by 50 mg/kg in 5% dextrose over 4 hours, and followed by 100 mg/kg in 5% dextrose over 16 hours. Ongoing administration at doses of 150 mg/kg over a 24-hour period may be indicated.

Even late administration of *N*-acetylcysteine (up to 36 hours after ingestion) may improve outcome. The risk factors listed in **Table 44.1.4**[2] confer a predisposition to paracetamol-induced hepatotoxicity:

The Prescott nomogram (**Fig. 44.1.2**) is used in the UK and Europe to determine the risk of acetaminophen

Table 44.1.3 Aetiology of acute liver failure and initial investigations

Hepatitis A (HAV)	Immunoglobulin M (IgM) anti-HAV
Hepatitis B+D (HBV, HDV)	HBsAg, IgM anti-core, HBeAg, HBeAb, HBV DNA, delta antibody
Hepatitis E (HEV)	IgM antibody
Seronegative hepatitis	All tests negative: diagnosis of exclusion
Paracetamol	Drug levels in blood and clinical pattern of disease – may be negative on third or subsequent days after overdose; markedly elevated aspartate and alanine serum transaminase (often >10 000)
Idiosyncratic drug reactions	Eosinophil count may be elevated, although most diagnoses are based on temporal relationship
Ecstasy	Blood, urine, hair analysis and history
Autoimmune	Autoantibodies, immunoglobulin profile
PREGNANCY-RELATED SYNDROMES	
Fatty liver	Uric acid elevated, neutrophilia, often first pregnancy, history, CT scan for rupture and assessment of vessels
HELLP syndrome	Platelet count, disseminated intravascular coagulation a prominent feature; CT scan as above
Liver rupture	May be seen in association with pre-eclampsia, fatty liver and HELLP
Wilson's disease	Urinary copper, ceruloplasmin (although low in many causes of acute liver failure), present up to second decade of life, Kayser–Fleischer rings, low alkaline phosphate levels
Amanita phalloides	History of ingestion of mushrooms, diarrhoea
Budd–Chiari syndrome	Ultrasound of vessels (HV signal lost, reverse flow in portal vein), CT angiography, ascites, prominent caudate lobe on imaging, haematological assessment
Malignancy	Imaging and histology; increased alkaline phosphate and LDH; often imaging may be interpreted as normal
Ischaemic hepatitis	Clinical context, marked elevation of transaminases (often >5000); may demonstrate dilated hepatic veins on ultrasound, echocardiogram
Heatstroke	Myoglobinuria and rhabdomyolysis are often prominent features

CT=computed tomography; HELLP=**h**aemolysis (microangiopathic haemolytic anaemia), **e**levated **l**iver enzymes and **l**ow **p**latelets; HIV=human immunodeficiency virus; LDH=lactate dehydrogenase.

Figure 44.1.1 A collapsed liver in the case of a 42-year-old man with ALF.

Table 44.1.4 Risk factors for paracetamol hepatotoxicity

DECREASED HEPATIC GLUTATHIONE STORES	INDUCTION OF CYTOCHROME P450
Anorexia nervosa	Phenytoin
Bulimia	Carbamazepine
HIV	Rifampicin
Cystic fibrosis	Phenobarbital
Malnourishment	Long-term ethanol ingestion

Greene et al. Postgrad Med J 2005;81:204–16 (published by BMJ group).[2]

toxicity. It can be applied only to a single acute overdose presenting within 16–24 hours.

If in doubt, commence treatment. NAC administration can be life saving, and adverse reactions and unpleasant side-effects are rare.

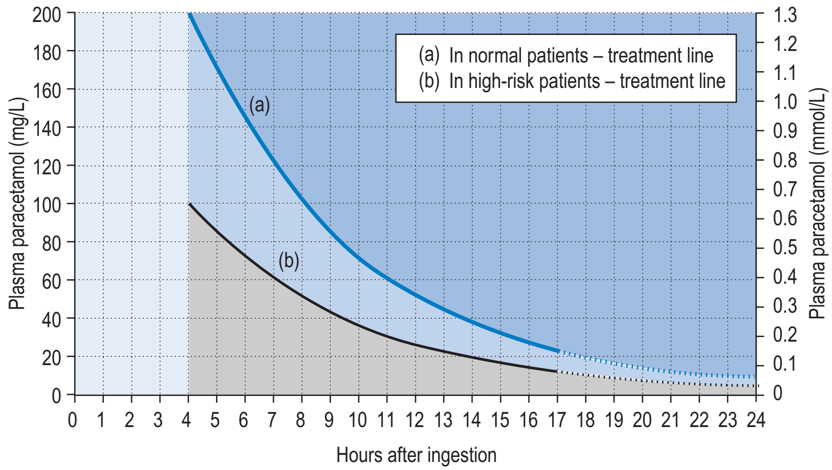

Figure 44.1.2 The Prescott nomogram.

It should be noted that negative paracetamol levels 16–24 hours after ingestion do not exclude the potential for hepatotoxicity. A staggered overdose is said to have occurred where there have been multiple ingestions over a period of time. Overdoses may be intentional or unintentional. Combined analgesics confer a risk of inadvertent overdose when they are abused for their narcotic content. A clear and detailed history is extremely important.

Patients with features of moderate or severe overdose should be managed in a critical care environment; the importance of early appropriate fluid resuscitation should not be underestimated. Contact should be made with a tertiary centre, and cases discussed with decision to transfer made in a timely fashion.

Early signs of nausea and vomiting after overdose are followed by signs of liver failure (see below) 48–72 hours after ingestion.

ACUTE VIRAL HEPATITIS

Acute viral hepatitis accounts for 40–70% of patients with ALF worldwide.

Acute hepatitis A (HAV) infection rarely leads to ALF (0.35% of infections), but continues to account for up to 10% of cases; morbidity increases with the age of infection. It is hoped that the prevalence will decrease with improving hygiene standards generally and the uptake of vaccination.

Acute hepatitis B (HBV) causes 25–75% of viral hepatitis-induced ALF. The liver injury is immunologically mediated with active destruction of infected hepatocytes. Diagnosis is by the presence of the IgM antibody (HBcAb) to hepatitis B core antigen. Hepatitis B surface antigen (HbsAg) is frequently negative by the time of presentation. Hepatitis B DNA should also be assayed. ALF may also be seen with hepatitis D, as either a co-infection or supra-infection.

Re-activation of hepatitis B is an increasing cause of ALF and should always be considered in a patient who has received steroids or chemotherapy. High-risk patients should be screened for sAg and HBV DNA and treated with antiviral agents if they are positive. This is a recognised problem in oncology and haematology but it is also a potential risk to patients in intensive care where steroids may be administered.

Hepatitis C (HCV) infection is commonly associated with chronic liver disease but *not* with ALF. It is detected by the presence of antibodies to HCV in serum. HCV-related cirrhosis will be discussed in detail in the subsequent chapter.

Hepatitis E (HEV), like hepatitis A, is transmitted via the faecal–oral route. It is particularly prevalent in the Indian subcontinent and Asia generally and is responsible for sporadic instances of ALF in the western world. It can be diagnosed by the detection of antibodies to HEV in serum.

Other viruses, such as herpes simplex 1 and 2, varicella zoster virus, cytomegalovirus, Epstein–Barr virus and measles virus, may all rarely cause ALF, but may be seen especially in the immunocompromised patient. Diagnosis is by serological and polymerase chain reaction (PCR) testing. Rift Valley fever, dengue, yellow fever, lassa fever and the haemorrhagic fevers should be considered in those who are at risk.

SERONEGATIVE HEPATITIS

Seronegative hepatitis (so called) is seen in patients in whom there are no identifiable viral causes or obvious candidate drugs. Such patients may present with a prodromal illness and with acute or subacute manifestations of the disease. Prognosis is less good than those with an identifiable virus and once they have poor prognostic criteria the chances of survival without liver

transplant are exceptionally small. A subgroup may represent an acute autoimmune form of ALF, although many will not have any positive immune markers such as elevated IgG or positive smooth-muscle or liver kidney antibodies. The pattern of markers shows an increased incidence of autoantibody positivity in seronegative cases and viral cases with elevated IgM in viral causes.[3,4]

DRUG-INDUCED LIVER INJURY (DILI)

Drug-induced hepatitis is responsible for approximately 15–25% of cases of ALF. In some patients there appears to be a true hypersensitivity reaction, and symptoms develop after a sensitisation period of 1–5 weeks, recur promptly with re-administration of the drug and may be accompanied by fever, rash and eosinophilia. In others the clinical pattern is less acute. Some herbal remedies are implicated as putative hepatotoxins, but their role is made more difficult to assess by the variable nature of the constituent parts. Halothane hepatitis is now almost unheard of.

RECREATIONAL DRUGS AND LIVER FAILURE

Ecstasy (methylenedioxymethamphetamine) may cause ALF although, given the prevalence of exposure to the drug, the incidence is presumably low. Proposed mechanisms of injury include immune-mediated mechanisms and/or heatstroke. Cocaine use may result in ischaemic hepatitis. Yellow phosphorus, carbon tetrachloride, chloroform, trichloroethylene and xylene (glue sniffing) are very rare causes of ALF.

AMANITA PHALLOIDES

Mushroom poisoning can be seen even when only very small amounts have been ingested (e.g. *Amanita phalloides*). The initial presentation is often with diarrhoea. Patients subsequently develop signs of hepatic necrosis at 2–3 days after ingestion. The liver injury is caused by amatoxins. Forced diuresis may be helpful as large amounts of toxin are excreted in urine, but inadvertent dehydration may result in renal failure. Thioctic acid, silibinin (silybin) and penicillin have been advocated as therapy, but have not been subjected to controlled trials.

FULMINANT WILSON'S DISEASE

The characteristic features are those of cirrhosis, seen on imaging, with concomitant problems such as thrombocytopenia that may be long-standing, Kayser–Fleischer rings on examination and frequently non-immune-mediated haemolysis.

ACUTE BUDD–CHIARI SYNDROME (HEPATIC VENOUS OBSTRUCTION)

Hepatic venous obstruction (Budd–Chiari syndrome) may cause ALF. There are symptoms and signs of liver of necrosis, often with capsular pain from congestion and ascites. In Asia this may be associated with anatomical anomalies of the inferior vena cava, whereas in Europe and the USA the experience is normally of thrombosis of the hepatic veins, often with an underlying procoagulant condition (**Fig. 44.1.3**).

ISCHAEMIC HEPATITIS

Heat shock injury is now relatively rarely seen but ischaemic hepatitis remains relatively common. They are normally associated with a congested liver that is subjected to a secondary insult – hypoxia or decreased-flow arterial inflow. This is seen with hypoxaemic respiratory failure, cardiac arrhythmias and hypotension.

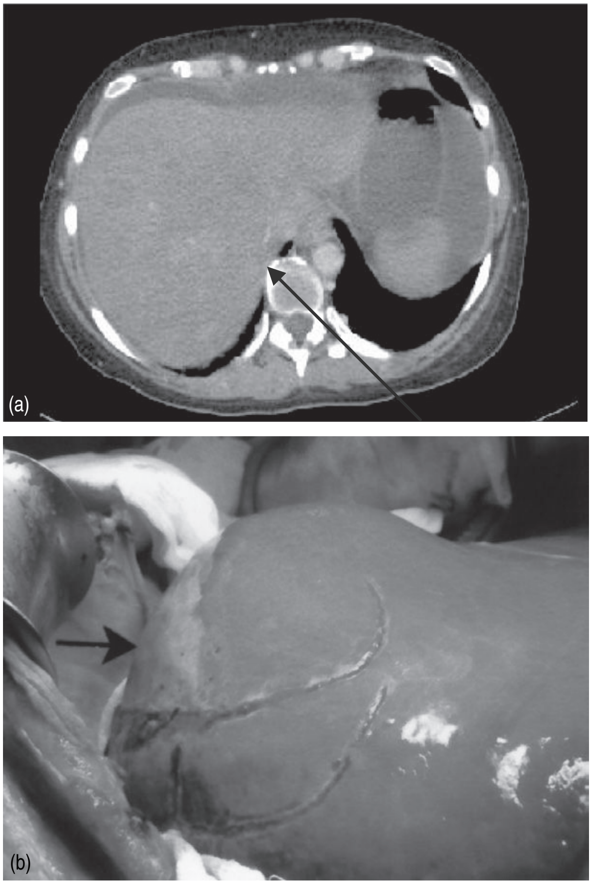

Figure 44.1.3 (a) Acute Budd–Chiari syndrome: The intrahepatic IVC is grossly attenuated. (b) Budd-Chiari liver: The arrow shows liver necrosis; ischaemic/infarcted liver.

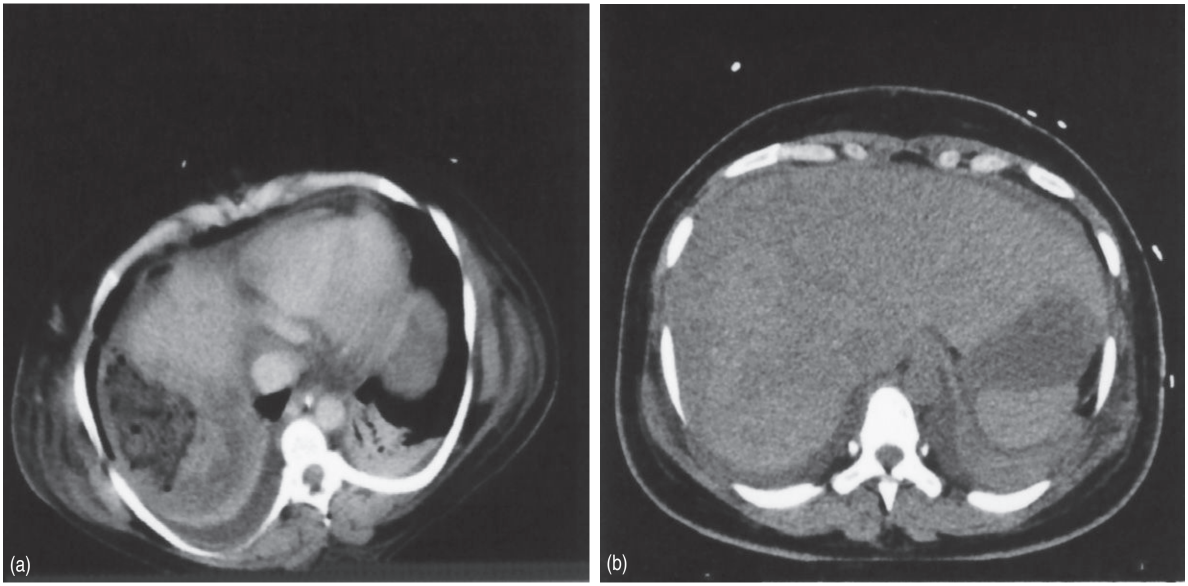

Figure 44.1.4 Liver CT in pregnancy-related liver disease demonstrating abnormal perfusion (a and b) with rupture, packing (a) and associated areas of infarction. Major bleeding into the liver.

PREGNANCY-RELATED ACUTE LIVER FAILURE

Pregnancy-related liver failure includes HELLP (**h**aemolysis (microangiopathic haemolytic anaemia), **e**levated **l**iver enzymes and **l**ow **p**latelets), acute fatty liver of pregnancy and liver rupture, often in association with pre-eclampsia. The prognosis of pregnancy-related ALF is usually good, although some develop severe liver injury with small-vessel disease, liver ruptures may require packing and occasionally transplantation is required (**Fig. 44.1.4**)

MALIGNANCY

Malignancy may also present with ALF, albeit rarely. The clinical pattern normally is that of elevated biliary enzymes in addition to the transaminases. This pattern of disease may be seen in those with hepatic lymphoma, often with an elevated lactate dehydrogenase or indeed with diffuse infiltration with other malignancies.

CLINICAL FEATURES

JAUNDICE

The classification above uses the time from jaundice to encephalopathy to describe ALF as either hyperacute, acute or subacute. In hyperacute liver failure (paracetamol toxicity, *Amanita* poisoning, acute viral hepatitis), encephalopathy may precede the onset of clinical jaundice.

Acute liver failure is frequently accompanied by a rapidly progressive syndrome of multi-organ failure requiring high levels of organ support.

HEPATIC ENCEPHALOPATHY

Hepatic encephalopathy is described by the modified Parsons–Smith scale (**Table 44.1.5**), which is based on functional impairment, changes in consciousness, cognitive function and behavior. The presence of encephalopathy is essential for a diagnosis of acute liver failure.

INTRACRANIAL HYPERTENSION

Hepatic encephalopathy is frequently complicated by cerebral oedema and intracranial hypertension with diminished cerebral perfusion and a risk of transtentorial herniation. The onset is rapid and allows little time for adaptive mechanisms (in contrast to patients with chronic liver disease where there is time for adaptation and control of cellular osmolarity). This has a significant implication in terms of the transfer of patients with ALF between hospitals. Intubation and ventilation with adequate sedation and implementation of neuroprotective strategies (see below) should be considered prior to transfer in any patient with progressive encephalopathy.

Patients with high-grade encephalopathy (coma) are at greatest risk of developing cerebral oedema. Elevated arterial ammonia levels, a higher MELD (model for end-stage liver disease) score, younger age, and requirement for vasopressor and renal replacement therapy are independent risk factors for hepatic encephalopathy and arterial ammonia levels >200 μmol/L are associated with cerebral herniation.[5,6]

Ammonia is produced by bacteria in the bowel and is taken up by cerebral astrocytes for deamination to

Table 44.1.5 Modified Parsons–Smith scale of hepatic encephalopathy

GRADE	CLINICAL FEATURES	NEUROLOGICAL SIGNS	GLASGOW COMA SCORE
0/subclinical	Normal	Seen only on neuropsychometric testing	15
1	Trivial lack of awareness, shortened attention span	Tremor, apraxia, incoordination	15
2	Lethargy, disorientation, personality change	Asterixis, ataxia, dysarthria	11–15
3	Confusion, somnolence to semi-stupor, responsive to stimuli	Asterixis, ataxia	8–11
4	Coma	±Decerebration	<8

glutamine. Water then moves into the intracellular compartment down its osmotic gradient. There are also induced changes in neurotransmitter synthesis and release, mitochondrial function and neuronal oxidative stress. The net result is astrocyte swelling and cerebral oedema.[7,8]

The association between the development of encephalopathy and markers of inflammation is well demonstrated, both in regard to systemic inflammatory response syndrome (SIRS) markers and inflammatory mediators such as tumour necrosis factor.[9,10] Curiously, a similar relationship between inflammation and encephalopathy is seen in patients with CLD.[11] What is not yet clear is whether treatments that modulate the inflammatory response will be of benefit. This and other avenues proposed from basic animal research may well result in several novel approaches to the treatment of cerebral oedema and possibly encephalopathy over the forthcoming years.

Blood–brain barrier injury, increased cerebral blood flow and hyperemia accompanying astrocyte swelling can potentiate cerebral oedema independently of astrocyte glutamine concentration. Thus, cerebral oedema may be vasogenic with inflammatory disruption of the blood–brain barrier or cytotoxic with osmotic dysregulation.

Blood flow is intimately coupled to cerebral metabolic rate, arterial oxygen and carbon dioxide tensions and acid–base status. The 'toxic liver hypothesis' describes the situation whereby there is a massive release of pro-inflammatory cytokines in association with the profound systemic inflammatory response and accumulation of toxic metabolites that accompanies acute liver failure. Altered cerebral blood flow and loss of autoregulation occurs in the face of this inflammatory milieu.

The Munro–Kellie hypothesis states that the intracranial cavity is essentially an incompressible box and that any increase in the volume of one of the intracranial components (blood, brain, CSF) must be accompanied by a decrease in the volume of another. CT studies have demonstrated effacement and ventricular attenuation are frequent radiological findings.

Diencephalic transtentorial herniation causes posterior cerebral artery insufficiency with temporal, thalamic, and occipital infarction; obstructive hydrocephalus; and brainstem ischaemia, compression and death.

The normal range for intracranial pressure is between 7–15 mmHg (0.93–2 kPa) in the supine adult. Many definitions of intracranial hypertension have been volunteered, but a pressure of >20 mmHg (2.66 kPa) for a period of 20 minutes should be considered worthy of treatment. The USALFG (US acute liver failure study group) recommend osmotic therapy for patients with an ICP >25 mmHg (3.33 kPa).[12]

The clinical management of the cerebral complications of ALF has been developed pragmatically and by the extrapolation of data from the neurosurgical literature. The use of intracranial pressure monitoring is controversial. Advocates would point out that clonus, brisk reflexes and hypertonicity can be detected clinically, but pupillary changes, systemic hypertension and reflex bradycardia are not apparent until intracranial hypertension is established, and that radiographic changes are non-specific. Sceptics would point out that there is no RCT evidence supporting an outcome benefit associated with intracranial pressure monitoring in ALF and that insertion confers a risk of intracranial haemorrhage. The USALFG found bleeding complications in up to 10% of patients, although many institutions use parenchymal monitors, which may be more accurate but confer a higher bleeding risk. At the authors' institution, standard practice is to use an epidural bolt – which may be slightly less accurate but confers a bleed rate of <1%. Bleeding associated with monitor insertion may be minimised by appropriate coagulation support at the time of placement. Some centres support coagulation at the time of insertion with plasma products and platelets whereas others use recombinant factor VII.

Standard practice in the authors' institution is that patients whose conscious level deteriorates to grade 3/4 coma are electively intubated, sedated and ventilated. A combination of opiate (e.g. fentanyl) and propofol is commonly used. The decision to move to ICP

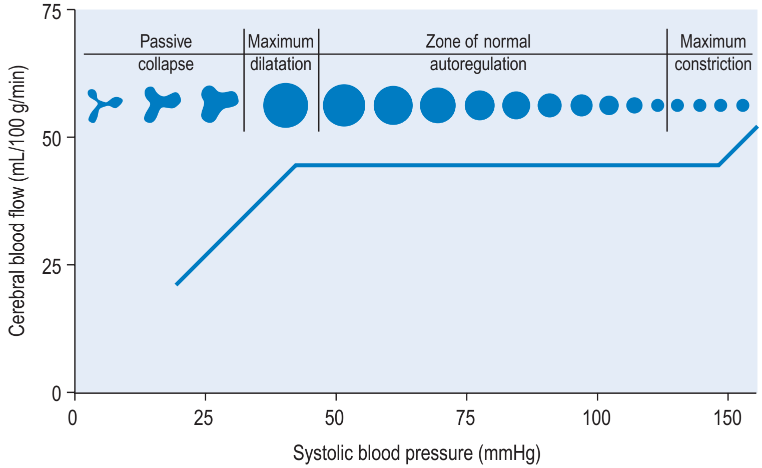

Figure 44.1.5 The relationship between SBP and CBF. Autoregulation may be lost, however, with flow pathologically dependent on pressure.

monitoring is highly individual and is supported by a hyperacute presentation, younger age and higher arterial ammonia levels (>150 mmol/L). Decision making is frequently supported by reverse jugular venous oximetry and Doppler estimation of middle cerebral arterial flow.

A cerebral perfusion pressure of >50 mmHg (6.66 kPa) has been suggested as optimal. It is of note that patients with ALF often do not autoregulate to pressure and consequently increases in blood pressure may be associated with increased cerebral blood flow and potentially increased ICP, particularly if they are at a critical point on their pressure–volume curve. Sustained cerebral perfusion pressures <40 mmHg (5.33 kPa) have been associated with very poor outcomes in some studies,[13] whereas others report good outcome despite periods of cerebral hypoperfusion (**Fig. 44.1.5**).

Invasive cardiovascular monitoring is mandatory (the authors advocate flow monitoring to guide fluid resuscitation). Norepinephrine (noradrenaline) and vasopressin are commonly used pressor agents. The use of terlipressin was associated with a rise in intracranial pressure in one study.[11]

In most patients, maintenance of P_{CO_2} 4.5–5.0 kPa is considered ideal. Cerebral blood flow is intimately coupled to arterial carbon dioxide tension and minute ventilation must therefore be carefully controlled. Lung injury/ARDS is relatively common and so protective ventilation strategies should be utilised.

Hyponatraemia and hyperammonaemia have been shown to be detrimental, whereas a randomised controlled trial showed benefit to the patients whose serum Na was maintained between 140 and 150 mmol/L. The use of hypertonic saline has been associated with a significant reduction in ICP, although the same study was not powered to detect a difference in outcome.

First-line treatment of a sustained rise in ICP remains mannitol 0.5 g/kg given as a bolus with an appropriate subsequent diuresis. It is essential that serum osmolarity is maintained at less than 320 mOsm to avoid damage to the blood–brain barrier and worsening of vasogenic oedema. Hypertonic saline is increasingly used in this setting.

Hypothermia has been shown to reduce cerebral blood flow, ICP and cerebral ammonia uptake.[14,15] The role of hypothermia as an early preventive intervention in grade III/IV coma is contentious and the results of controlled studies are awaited. Fever should be avoided.

Other treatment options that have been shown to be potentially beneficial are thiopental and intravenous indomethacin (0.5 mg/kg).[16] Potential monitoring and treatment algorithms, as used by this unit, are detailed in **Figure 44.1.6**.

SEPSIS

Sepsis is common in ALF and both culture-positive and negative SIRS are seen. Patients are functionally immunosuppressed in terms of impaired cell-mediated immunity, complement levels and phagocytosis.[17] Functional immmunoparesis can only be observed and depression of human leucocyte antigen (HLA) DR expression correlates with prognosis and severity of liver injury.[18,19] As such, scrupulous attention with regard to hand washing and line care needs to be applied to decrease the risk of nosocomial infection. Regular culture screens are required and antimicrobials are indicated in patients with any clinical suggestion of sepsis. Prophylactic intravenous antifungals should be considered, especially in those listed for transplantation. The choice of antimicrobial agent should be driven by local resistance patterns. Antimicrobial therapy should be reviewed in the light of culture results on a daily basis.

COAGULOPATHY

Coagulopathy is the hallmark of ALF, with prolongation predominantly of the prothrombin time and to lesser degrees the activated partial thromboplastin ratio

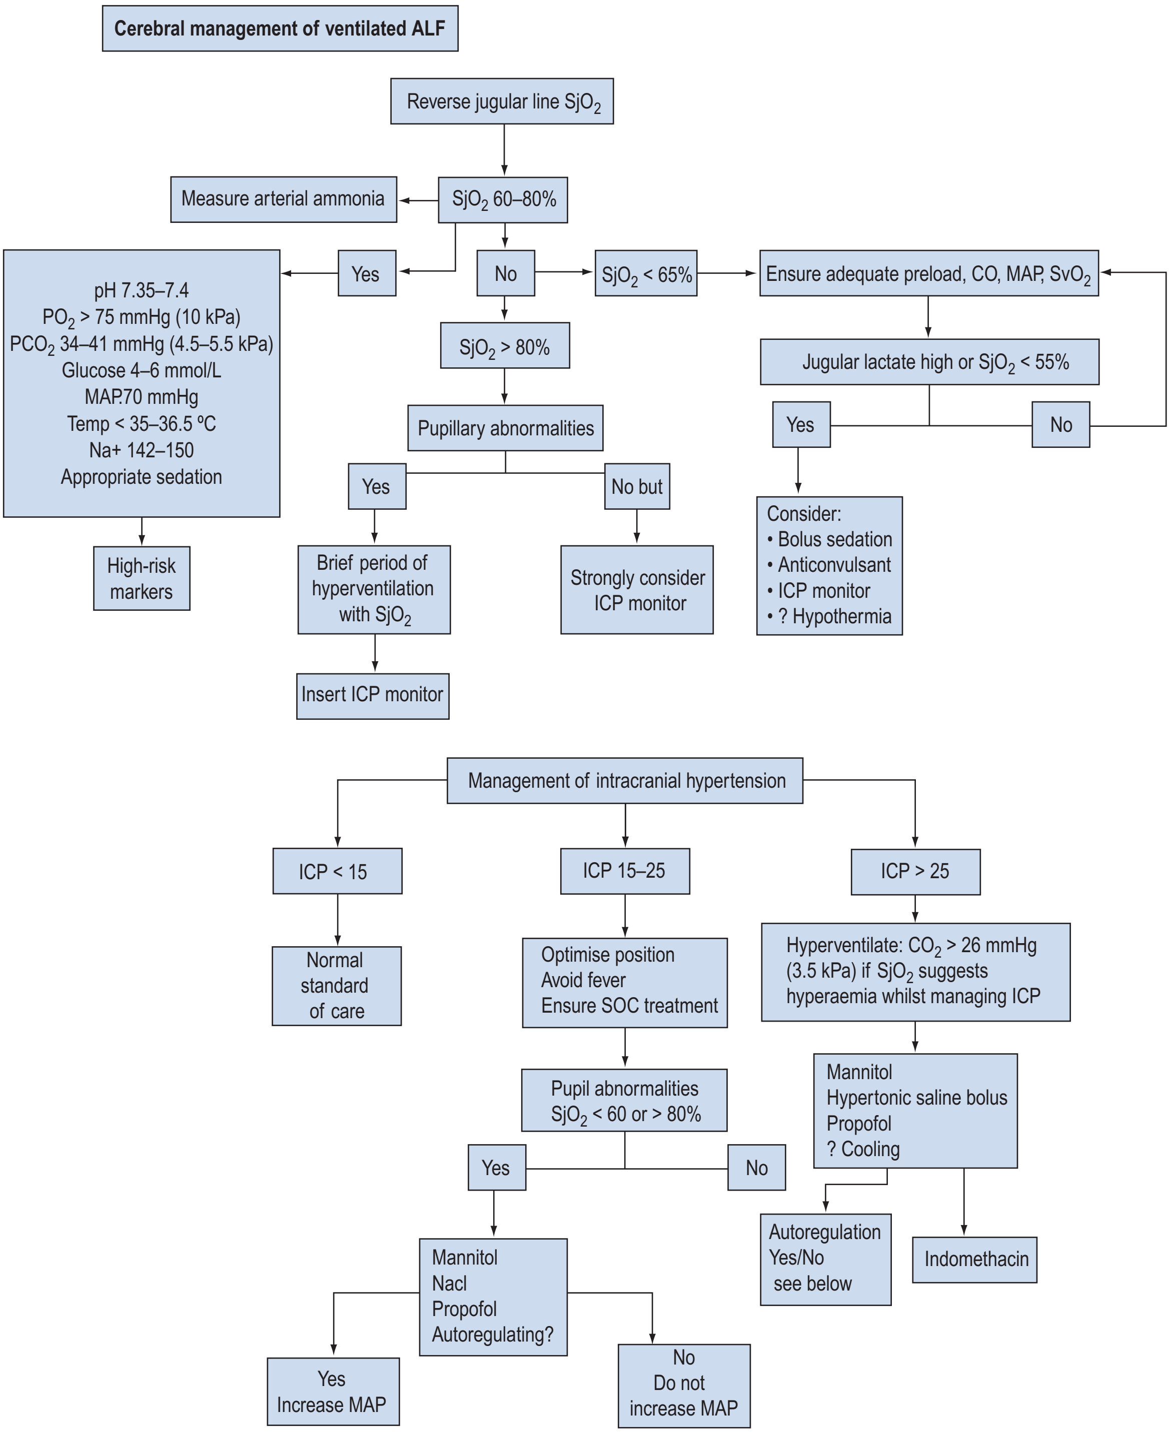

Figure 44.1.6 Treatment of raised intracranial pressure.

(APTR). In a small percentage of patients the coagulopathy will respond, at least partially, to vitamin K. Intravenous vitamin K 10 mg is normally administered. Thrombocytopenia is common and frequently consumptive in nature. Bleeding is rare, although may be seen in those with severe prolongation of APTR, low fibrinogen and severe thrombocytopenia. Coagulation or repletion of coagulation factors is necessary for clinical bleeding and prophylactically before major invasive procedures. Coagulation support is normally not given routinely so that the international normalised ratio (INR) can be monitored with regard to prognosis.

CARDIOVASCULAR CONSIDERATIONS

Patients with ALF develop a hyperdynamic circulation with peripheral vasodilation and central volume depletion. Hypotension is common and may initially respond to volume repletion. Assessment of volume responsiveness in the clinical setting may be difficult and pressure measurements are a poor indicator of volume status. Hypotension that does not respond to volume will normally require some form of invasive haemodynamic monitoring and frequently institution of vasopressor agents. Increasingly it is recognised that volume responsiveness, as in general intensive care unit patients, is best determined by dynamic rather than static variables.

The requirement for pressor agents should raise the possibility of adrenal dysfunction. Patients with ALF have been demonstrated to have impaired responses to adrenocorticotropic hormone (ACTH).[20,21] The response at 30 and 60 minutes in terms of cortisol should be examined following 250 µg ACTH in all patients with ALF who are requiring pressor agents. A subnormal response should result in consideration of hydrocortisone replacement therapy, normally given for a period of 10 days. Interestingly, adrenal dysfunction has similarly been reported in acute-on-chronic liver failure and steroid replacement may result in improved outcome.[21,22]

Elevated troponin levels can be observed in patients with liver failure, especially those with cardiovascular failure.[23]

RESPIRATORY CONSIDERATIONS

Ventilatory support is frequently required in patients with ALF, usually because of decreased conscious level rather than hypoxia, at least in the initial stages of disease.

Common respiratory complications are pleural effusions, atelectasis and intrapulmonary shunts. Acute respiratory distress syndrome (ARDS) and acute lung injury may be seen and can be precipitated by extrapulmonary sepsis or inflammation.

Ventilatory strategies are influenced by both the respiratory and the multiorgan involvement that is characteristic of ALF. Thus patients with deep levels of coma and at risk of cerebral oedema will require close attention to CO_2 levels and tailored sedation regimens. Hypercapnia may have to be tolerated in patients progressing to ARDS. This requires balancing against the cerebral needs of these patients as hypercarbia and increased cerebral blood flow will tend to increase ICP. Pleural effusions may require drainage if they are impeding ventilation. Weaning may be facilitated by undertaking tracheostomy during the recovery period of ALF.

RENAL CONSIDERATIONS

Renal failure is common, with an incidence as high as 50%. This is particularly the case with paracetamol-induced liver failure, where the drug may also exert a directly toxic effect on the renal tubule. The aetiology of acute renal dysfunction is frequently multifactorial, with hepatorenal failure being a rare occurrence. Acute tubular necrosis and pre-renal renal failure are common. As such, volume therapy and maintenance of intrathoracic blood volume are essential in the management of such patients, as is the avoidance of nephrotoxins. Intra-abdominal hypertension is frequent and may reduce renal perfusion pressure and contribute to renal dysfunction; the measurement of intra-abdominal pressure may be a valuable component of monitoring.

Established renal failure requires the institution of renal replacement therapy (RRT). In patients with ALF early consideration should be given to RRT to control fluid balance and acid–base disturbances and to avoid rapid changes in osmolarity. It may limit or control elevations of arterial ammonia and retard the development of cerebral complications. The haemodynamic instability and associated cerebral complications of this patient group have resulted in the application of continuous modes of RRT rather than intermittent haemodialysis. Inability of the liver to metabolise and utilise lactate or acetate buffer solutions results in the use of bicarbonate buffers.

A balance needs to be achieved between risk of bleeding and platelet protection across an extracorporeal filter. A prostaglandin such as epoprostenol may be advantageous in terms of decreasing bleeding and prolonging filter life. Alternatively, circuits may be run without anticoagulation, with regional heparin or citrate or low-dose systemic heparin. In patients with thrombocytopenia, consideration should be given to the diagnosis of heparin-induced thrombocytopenia and, if confirmed, heparin should be withdrawn and circuits primed with an alternative agent (e.g. danaparoid).

METABOLISM AND FEEDING

Enteral nutrition should commence as soon as feasible after admission if there are no contraindications. In patients with large aspirates (>200 mL/4 h) a prokinetic agent should be commenced: erythromycin

(250 mg intravenously 6-hourly) appears to be more effective than metoclopramide. Endoscopic placement of a post-pyloric feeding tube should be considered in refractory cases, although this may need to be delayed in patients with or at risk of cerebral oedema. In patients with profound coagulopathy, placement of a nasogastric tube may be associated with nasal/pharyngeal bleeding and oral tube placement may be preferred in ventilated patients. The optimal nature of enteral feed used has not been investigated but metabolic data on these patients demonstrate increased calorific requirements.[24,25] Patients with ALF demonstrate both peripheral and hepatological insulin resistance.[26] Tight glycaemic control would seem reasonable in this population.

Metabolic acidosis is a relatively frequent occurrence that may relate to lactic acidosis, hyperchloraemic acidosis or renal failure.

Hyperlactataemia may be secondary to volume depletion and hence will resolve with appropriate fluid loading or may reflect the inability of the liver to metabolise the lactate produced. A failure of blood lactate to normalise following volume loading is associated with a poor prognosis.[26,27] Metabolic acidosis may be a secondary effect of other drugs ingested as part of an episode of self-harm. Falls in serum phosphate levels are seen in ALF associated with liver regeneration and are associated with a good prognosis in paracetamol-induced ALF.[28] Pancreatitis is a common complication of ALF and should be actively sought.

SPECIFIC TREATMENTS

The management of ALF is largely supportive, providing an optimal environment for either regeneration or stability until a suitable liver becomes available. Once patients develop poor prognostic criteria the chances of effective liver regeneration and thus of spontaneous recovery are low; the prognosis is very poor without liver transplantation. The role of extracorporeal liver support systems remains a hope for the future but at present no system has been shown to have a definitive survival benefit in a controlled trial.

- *N*-acetylcysteine is administered for paracetamol-induced ALF, as mentioned above. Its role in non-paracetamol-induced ALF remains undefined although a US study[29] suggests that it may be of benefit in patients with ALF and grade 1–2 encephalopathy (presumably because transplantation is required to impact on outcome when higher grades of encephalopathy are achieved).
- Chelating agents are not of benefit in patients with established ALF secondary to Wilson's disease but play an important role in chronic presentations. Withdrawal of such treatments, or indeed non-compliance, especially in teenagers, may precipitate ALF.
- Antiviral therapy has a predominant role in preventing re-activation of hepatitis B in patients exposed to chemotherapy and steroids.
- Thrombolytic therapies may be of benefit in patients with early acute Budd–Chiari syndrome, although increasingly the treatment option would be to undertake a transhepatic portosystemic shunt (TIPS) shunt, decompressing the liver with a stent passed either through the hepatic vein (if the clot is soft enough) or via the inferior vena cava and through to the portal vein. Such procedures should be undertaken in units with the facilities to transplant as there is a risk of precipitating ALF. Chemotherapy may be offered to those with lymphoma involving the liver and in these instances tissue is paramount, either of liver or from another diagnostic site.
- Steroid therapy is beneficial in acute autoimmune hepatitis but its role in autoimmune ALF has been less clear. A recent publication from the Paris group suggests that steroids for those with established ALF are potentially detrimental.[30]

PROGNOSIS

Prognostication is important in the management of ALF. It is essential to identify those patients who will not survive without liver transplant but also to identify those who will succumb even if offered such a procedure.[31] Several risk stratification systems are presented in **Box 44.1.2**. The most commonly used are those of

Box 44.1.2 Prognostic criteria for acute liver failure

O'Grady criteria

Paracetamol-related

Acidosis (pH <7.3), *or*

Prothrombin time of >100 seconds (INR >6.5), creatinine >300 mol/L and grade III/IV encephalopathy – all occurring within a 24-hour timeframe

Non-paracetamol-related

Any three of the following in association with encephalopathy:

Age less than 10 or greater than 40 years

Bilirubin >300 mol/L

Time from jaundice to encephalopathy >7 days

Aetiology: either non-A, non-B (seronegative hepatitis) *or* drug-induced

Prothrombin time >50 seconds, *or*

Prothrombin time >100 seconds/INR >6.5

French criteria (Clichy criteria)

The criteria are the presence of encephalopathy (coma or confusion), *and*

Age <20 years with factor V level <20%, *or*

Factor V levels <30% if greater than 30 years of age 59

INR = international normalised ratio.

O'Grady and Clichy. The model for end-stage liver disease (MELD) has also been examined with regard to prognosis in ALF and may be particularly useful in non-paracetamol cases.[32] It is essential that such systems are rigorously applied and in the context of paracetamol are only utilised at least 24 hours post-ingestion and following appropriate volume resuscitation.

44.2 Cirrhosis and acute-on-chronic liver disease

Chronic liver disease is said to be evident when liver dysfunction has been present for a period >6 months. It presents far more commonly to the intensive care unit than does acute liver failure. Acute decompensations in hepatic and extrahepatic organ function in the previously stable cirrhotic are frequently precipitated by infection and bleeding (often variceal), but may also reflect a trajectory of decline in liver function in a patient with end-stage disease. Acute decompensations are termed *acute on chronic liver failure* (ACLF).

AETIOLOGY OF CHRONIC LIVER DISEASE

There are myriad causes of chronic liver disease. Those most frequently encountered are listed in **Box 44.2.1**. It is beyond the scope of this chapter to discuss these in any depth – but we will focus on the management of decompensations, complications and extrahepatic organ failure.

The ICU physician is seldom involved in the management of stable chronic liver disease. Acute on chronic presentations are relatively common, however, and patients with previously unrecognised cirrhosis may decompensate following unrelated medical interventions. Wherever possible, planned interventions in patients with documented cirrhosis should be undertaken in specialist centres with appropriated periprocedural supervision.

Box 44.2.1 Common aetiologies of chronic liver disease

- Chronic infection with hepatitis B and C viruses
- Alcohol
- Primary biliary cirrhosis
- Autoimmune chronic active hepatitis
- Primary sclerosing cholangitis
- Budd–Chiari syndrome
- Veno-occlusive disease
- Amyloidosis
- α_1-antitrypsin deficiency
- Wilson's disease

DECOMPENSATED CHRONIC LIVER DISEASE

ACLF commonly presents with one of the following:

- encephalopathy
- sepsis
- renal failure
- variceal bleeding
- cardiorespiratory failure.

The cause of decompensation should be sought in all cases when it is not clinically apparent. In addition to sepsis and bleeding, alcohol, dehydration, drug therapies (e.g. opiates and sedatives), hepatocellular carcinoma (HCC) and portal vein thrombosis should be considered. Ultrasound should be undertaken in all patients, examining the hepatic veins and portal veins for patency. In patients with ascites a diagnostic tap should always be undertaken for microbiological culture and cell count (a polymorphonuclear count >250/mm^3 is indicative of bacterial peritonitis).

Signs of HCC should be sought on ultrasound, alphafetoprotein and axial imaging techniques. The therapies available for HCC have improved dramatically in recent years and prognosis can be good, especially with the option of cure with liver transplantation.

ENCEPHALOPATHY IN CHRONIC LIVER DISEASE

Hepatic encephalopathy is frequently seen in patients with cirrhosis and a systemic inflammatory response (and so sepsis should be actively sought and treated). Encephalopathy in chronic liver disease has pathophysiological and clinical features that are different from those seen in acute liver failure. Importantly, the

cirrhotic cohort does not normally develop intracranial hypertension and as such the management centres on prevention of encephalopathy, the treatment of worsening encephalopathy and control of the airway and prevention of aspiration in those who are deeply encephalopathic.

Ammonia levels are frequently (but not always) elevated in encephalopathy and thus therapy includes bowel cleansing with agents such as lactulose and non-absorbable antibiotics such as rifaximin. There is little evidence-based research to support any particular avenue of treatment. A trial examining the role of albumin dialysis in the management of encephalopathy has been recently completed.[1]

As noted previously, the role of inflammation seems of importance in the development of encephalopathy.[2,3] As many as 70% of patients with bacteraemia demonstrate a 'septic encephalopathy' which manifests as lethargy, confusion, agitation or even coma. There is some evidence that pro-inflammatory mediators mobilised during systemic inflammatory response syndrome (SIRS)/sepsis modulate the action of ammonia on the brain. Shawcross et al in 2004[3] demonstrated that neuropsychological test scores deteriorate when hyperammonaemia is induced in cirrhotics with infection, during the inflammatory state, but not following its resolution. This synergism may be attributed to a number of possible mechanisms:[4]

- Higher levels of inflammatory cytokines such as IL-1, IL-6 and TNFα (see above) may act via activation of vagal afferents in the periphery, via cytokine receptors on the cerebral endothelial cell or have direct action on astrocytes
- The generation of reactive oxygen species and nitric oxide in astrocytes in hyperammonaemia and sepsis[4] with diminished activity of antioxidant enzymes[5]
- Dysregulation of cerebral blood flow, which occurs in cirrhosis, may be exaggerated in sepsis.

The prognosis in cirrhotic patients with sepsis is considerably worse following the onset of encephalopathy.

The role of feeding in the development of encephalopathy has always caused controversy. Recent guidance suggests that protein restriction is not appropriate and a study examining early versus slow introduction of protein into enteral nutrition showed no increase in encephalopathy and indeed appeared beneficial in respect of nitrogen balance.[6,7]

SEPSIS IN CHRONIC LIVER DISEASE

A classical definition of sepsis is SIRS in response to a proven or suspected microbial event. This definition may not be universally applicable, however. The compensated and decompensated cirrhotic may demonstrate components of SIRS under resting conditions. For example, cirrhotics often have an elevated resting heart rate with a hyperdynamic circulation, hyperventilation due to the evolution of hepatic encephalopathy and reduced baseline polymorphonuclear (PMN) count owing to hypersplenism. Indeed, the response of the cirrhotic patient to infection may be characterised only by an exacerbation of circulatory changes already present at baseline or may be distinctly uncharacteristic with, for example, blunting of the elevation in body temperature that is usually seen in sepsis.

The mortality of cirrhotic patients who fulfil SIRS criteria is significantly higher than in those who do not[8] and a majority of those with SIRS have intercurrent infection. It is often unclear whether SIRS acts as a predisposition to or is a consequence of infection in this cohort. In one retrospective analysis of non-transplanted patients with acute on chronic liver failure, bacteraemia was associated with increased illness severity, requirements for organ support, and mortality.[9] The same group found that severity of hepatic encephalopathy and SIRS score >1 were predictive of bacteraemia.[10]

Bacterial infections are more common in cirrhosis than in the general population, and are higher still during episodes of decompensation. Cirrhotic individuals are significantly more likely to die while hospitalised (adjusted risk ratio (RR) 2.7), to have hospitalisations associated with sepsis (adjusted RR 2.6) and to die from sepsis (adjusted RR 2.0).[11]

The increased incidence of sepsis in those with underlying liver disease is multifactorial. Patients are frequently physically debilitated, deconditioned, malnourished and cachectic. Bactericidal and opsonic activity is reduced. Monocyte function is altered and there is depression of the phagocytic activity of the reticuloendothelial system owing to the presence of intra- and extrahepatic shunts through sinusoids without Kupffer cells, and reduced Kupffer cell numbers and function.[12] Serum complement levels are low. Ascites and peripheral oedema are often present. Iatrogenic factors may be contributory. There may be an associated genetic susceptibility to severe infection and sepsis.

The acquisition of a sepsis syndrome is frequently accompanied by encephalopathy, renal failure and worsening coagulopathy. The in-hospital mortality of septic cirrhotics is, accordingly, much higher and has been recently estimated at 70%[13] and infection is responsible for 30–50% of deaths in patients with cirrhosis.[14]

The main sites of infection in cirrhosis are ascites, urinary tract, lungs and blood. The commonest organisms are *Escherichia coli*, followed by *Staphylococcus aureus*, *Enterococcus faecalis, Streptococcus pneumoniae, Pseudomonas aeruginosa,* and *Staphylococcus epidermidis*. However, resistant Gram-positive organisms and extended spectrum beta lactamase (ESBL)-producing enterobacteria are becoming increasingly common (particularly in nosocomial infection). Cephalosporins therefore fail in a substantial proportion of infections acquired during hospitalisation.

The epidemiology of sepsis in cirrhosis is in a state of flux. Resistant organisms are increasing in

prevalence both in nosocomial infection and in patients who require long-term antibacterial prophylaxis. Liver transplantation programmes have given chronic cirrhotics a chance of salvation, and encourage physicians to treat episodes of sepsis more aggressively than ever before. Surveillance and early diagnosis of infection, coupled with adequate and appropriate antibiosis have led to improved outcomes in cirrhotic patients with spontaneous bacterial peritonitis (SBP) and other severe infections.

An enhanced inflammatory response can cause an exaggerated and damaging inflammatory response that may provoke single of multiple organ failures. Organ failure is an important determinant of outcome in patients with cirrhosis, with mortality increasing with the number of organ systems failing. Single-organ failure carries confers a mortality of 33%, double-organ failures a mortality of 73% and three-organ failure a mortality of 97%.[15,16]

Tissue hypoperfusion occurs secondary to systemic hypotension, microvascular dysfunction, shunting, microthrombi formation, vasoplegia, and reduced RBC deformity and tissue oedema. Nitric oxide (NO) synthesis may be responsible for defective mitochondrial respiration. Direct tissue damage is caused by cellular infiltrates, particularly neutrophils releasing lysosomal enzymes and superoxide-derived free radicals.[17]

PATHOPHYSIOLOGY OF SEPSIS IN CIRRHOSIS

ENDOTOXIN SIGNALLING

Lipopolysaccharide (LPS) found on the outer membrane of Gram-negative bacteria and peptidoglycan (PGN) and lipopeptide (LP) from Gram-positive bacteria stimulate Toll-like receptors (TLRs). The interaction of ligand with receptor triggers innate pro-inflammatory signalling cascades[18] with rapid cytokine and chemokine release (**Fig. 44.2.1**).

The Gram-negative flora of the intestine provides a reservoir of LPS. LPS is absorbed and transported in the portal vein where it is rapidly cleared by Kupffer cells. Under normal circumstances the liver does not show signs of excessive inflammation. In addition to its ability to clear LPS, the liver also responds to LPS with the production of cytokines and reactive oxygen intermediates, primarily by Kupffer cells.

In many types of chronic liver disease, levels of endotoxin[19] are elevated and tend to increase progressively as liver function deteriorates. Mortality is higher in patients with significant endotoxaemia than in those without.[20]

Cytokines such as TNFα, IL-6, and IL-1 are essential components of the immune defence mechanism, but may propagate overwhelming septic shock. These may be over-produced and/or up-regulated in chronic liver

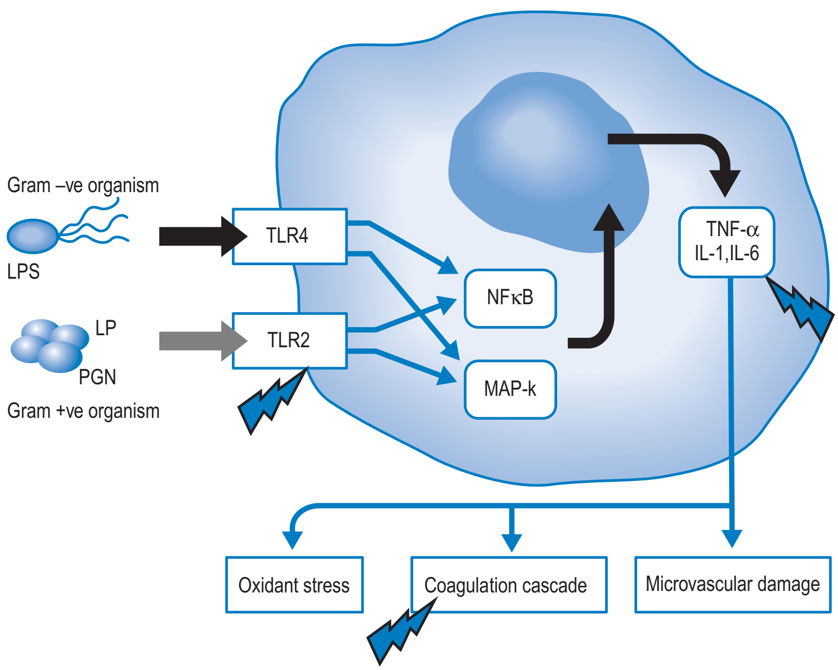

Figure 44.2.1 Endotoxin signalling pathway. The flashpoints represent changes in cirrhosis that make patients more susceptible to infection. LPS=lipopolysaccharide; LP=lipopeptide; PGN=peptidoglycan; TLR=Toll-like receptor; TNF=tumour necrosis factor; IL=interleukin; NFκB=nuclear factor-κB; MAP =membrane-associated protein. *(Reproduced with permission from Wong F, Bernardi M, Balk R, et al; International Ascites Club. Sepsis in cirrhosis: report on the 7th meeting of the International Ascites Club. Gut 2005;54:718–25.)*

disease, although the absolute levels of inflammatory cytokines are extremely variable in cirrhotic cohorts with septic complications. NO production is enhanced in cirrhosis, and is further increased in sepsis, with the induction of nitric oxide synthase (NOS) by LPS.

BACTERIAL TRANSLOCATION

Bacterial translocation is the migration of bacteria or bacterial products from the intestinal lumen to mesenteric lymph nodes or other extraintestinal organs and sites.[21] As mentioned above, elevated levels of endotoxin are a frequent finding in chronic liver disease, and levels tend to increase with disease severity (Child classification). Chromogenic assay in patients undergoing angiographic intervention demonstrates a gradient in terms of endotoxin level between portal and systemic circulations,[22] suggesting that the bowel is the source of the endotoxaemia.

Small bowel hypomotility, alterations in intestinal flora and disruption of mucosal barrier function promote bacterial translocation in the cirrhotic population. It is proposed that bacterial translocation is one of the main causes of spontaneous infection in this cohort and may perpetuate the persistent hyperdynamic state. Portal hypertension, ascites and increased severity of liver dysfunction are risk factors for bacterial translocation in this cohort. The epithelium demonstrates structural changes in cirrhosis, with widening of the intercellular spaces, and there is increased intestinal permeability.[23] Intestinal permeability is increased with portal hypertension (NO may be implicated in disruption of the intestinal epithelium).[24] Permeability is increased further if there is concomitant alcohol intake.

Organisms are usually removed from intestinal tissue by phagocytes. The intestinal immune system is centred on the gut-associated lymphoid tissue (GALT), which is comprised of Peyer's patches, lamina propria lymphocytes, intraepithelial lymphocytes, and mesenteric lymph nodes. The innate immune response is centred on stimulation of TLRs, a cytokine response and bacterial killing by monocytes and lamina propria lymphocytes. Under normal circumstances, any organism breaching the intestinal mucosal barrier is killed. Thus, in order for translocation to become clinically significant, there needs to be an overall failure of local and systemic immune defence.

The currently available therapies are directed towards reducing translocation either by promoting gut motility, decreasing bacterial overgrowth or changing the composition of the gut flora. Selective digestive decontamination has been shown to be effective in preventing infection in patients with gastrointestinal haemorrhage,[25] and in prophylaxis in patients with ascites.

IMMUNE PARESIS

As stated above, there is up-regulation of TLRs and increased levels of circulating cytokines and activation of monocytes in cirrhotics. This does not, however, correspond to increased bacterial killing. Rather, the innate immune system is impaired with decreased phagocytosis and opsonisation.[21] This has been described as a 'sepsis-like immune paralysis'.[26]

GENETIC SUSCEPTIBILITY

It is recognised that a genetic variables may confer a predisposition towards the acquisition of infection in cirrhotic patients.

The management of sepsis in patients with liver failure should proceed along the same lines as in the cohort without liver failure. However, consideration should be given some of the issues outlined below, which are peculiar to this population.

MANAGEMENT OF SEPSIS IN CIRRHOSIS

The principles of early goal-directed therapy in the treatment of sepsis are valid – that is, the early restoration of the circulating volume and maintenance of an adequate cardiac output, but the manner by which adequacy is assessed is complex. The circulation is frequently hyperdynamic in patients with acute or chronic liver failure – with or without infection. The oxygen extraction ratio is not uniform and shunting may occur. As a consequence, central venous oxygen saturations may be artificially high, and not representative of an inadequately resuscitated patient. Early goal-directed therapy titrated to central venous oxygen saturation as outlined by Rivers et al[27] may therefore not be applicable to this cohort. Furthermore, the use of the central venous pressure has been demonstrated to be unreliable[28] as a marker for preload-responsiveness. The authors would therefore advocate the early use of a cardiac output monitor, several of which are in widespread use. These provide markers of preload and preload responsiveness. Stroke volume response to fluid challenge or passive leg raising may be used in the mechanically ventilated or the spontaneously breathing patient.

Lactate levels have been used as markers of the adequacy of fluid resuscitation in sepsis.[29] In sepsis, lactate levels are elevated due to a higher metabolic rate, inhibition of pyruvate dehydrogenase and reflect uptake by the liver. In liver disease, this uptake is markedly diminished and elevated lactate levels may not, therefore, imply anaerobic metabolism. Lactate levels are therefore inadequate markers in this cohort, although elevated levels still unquestionably identify the sicker patients.

In terms of fluid resuscitation, albumin does not confer a mortality benefit over crystalloid in the critically unwell cohort. It does have a specific role in the treatment of patients undergoing large-volume paracentesis and has been demonstrated to preserve haemodynamics and attenuate a tendency towards hepatorenal syndrome.[30,31] A small, unblinded randomised controlled trial suggested that 20% albumin

was more effective in terms of improving systemic haemodynamics than a 6% HES solution in spontaneous bacterial peritonitis.[32]

Vasopressor therapy is often required for the maintenance of adequate mean arterial pressure. Norepinephrine (noradrenaline) is the most frequently used pressor agent in the author's unit, with α-agonism attenuating a vasodilated, hyperdynamic systemic circulation and β-agonism augmenting ventricular function (which is frequently impaired in this cohort). Dopamine has no benefit over norepinephrine in the critically unwell and may be associated with a greater number of adverse events.[33] It is also not preferred in the liver failure cohort as it may cause dilatation of the superior mesenteric artery, leading to increased portal pressures. Vasopressin is used in refractory shock and to mitigate very high norepinephrine requirements.

In general terms, ventilatory management should proceed as per management in the general intensive care cohort, with attention paid to protective ventilatory strategies if ARDS is clinically apparent (limiting tidal volumes to ~6 mL/kg and plateau pressure to <30 cmH_2O). Endotracheal intubation is performed for airway protection in advanced (grade III/IV encephalopathy and for the treatment of respiratory failure. It is worth noting that raised intracranial pressure is not normally a feature of chronic liver disease.

Both acute liver failure and chronic cirrhosis are hypermetabolic states with marked catabolism and a net negative nitrogen balance. Assessment of the degree of malnutrition and muscle wasting in the chronic cirrhotic is often difficult owing to the presence of ascites and oedema. Dysphagia and gastroparesis are common in patients with cirrhosis and portal hypertension[34] and the development of encephalopathy of any grade may be associated with a risk of aspiration. In both sepsis and liver failure the potential for both cholestasis and steatosis is significant. In the event of variceal bleeding, it is usual practice at the authors' institution to wait for 48 hours before placement of a nasogastric feeding tube owing to the risk of precipitating further bleeding. Immunonutrition has not been studied in critically unwell patients with liver failure.

The protein load associated with enteral feeding may predispose to hyperammonaemia, which is common in the (decompensated) cirrhotic. Lactulose, L-ornithine L-aspartate (LOLA) and non-absorbable antibiotics such as neomycin, rifaximin, metronidazole, oral vancomycin and oral quinolones have been administered in an effort to decrease the colonic concentration of ammoniagenic bacteria. Branched chain amino acid-enriched formulae may provide protein supplementation in the patient with troublesome hepatic encephalopathy.

Hyperglycaemia is common in sepsis and may be pro-coagulant, induce apoptosis and inhibit neutrophil function. Landmark clinical trials have suggested that the strict maintenance of glycaemic control is beneficial in critically unwell surgical patients.[35] The same group failed to demonstrate a mortality benefit in a medical cohort.[36] Meier el al[37] compared the consequences of intensive glycaemic control (3.5-6.5 mmol/L) with loose glycaemic control (5.0–8.0 mmol/L). The incidences of hypoglycaemia and of bacteraemia were higher in the tight control group, with a trend towards worsened survival at 21 days. There are no RCTs examining the efficacy of tight glycaemic control in the cirrhotic population and there is a high prevalence of hypoglycaemic events in this cohort.

The efficacy of high-volume CVVH in severe sepsis and septic shock has generated a great deal of interest in the critical care community in recent years. It is proposed that the removal of mediators of the inflammatory cascade such as IL-2, IL-6, IL-8, IL-10, TNFα, C3a and C5a may attenuate the inflammatory response, improving haemodynamics and thereby end-organ perfusion and function. Animal studies were initially encouraging. A series of observational, interventional, randomised (but small scale and uncontrolled) studies showed beneficial cardiovascular effects and an improvement in predicted hospital and 28-day mortality.[38] However, a recent large randomised study demonstrated that intensive renal support in critically ill patients with acute kidney injury did not decrease mortality, improve recovery of kidney function, or reduce the rate of non-renal organ failure as compared with less-intensive therapy.[39] There is consequently a lack of consensus on the optimal timing for the commencement of renal replacement therapy, the appropriate dose or the type of membrane (pore size, surface area) for critically ill patients. Data for the septic/cirrhotic cohort are lacking.

SPONTANEOUS BACTERIAL PERITONITIS

Spontaneous bacterial peritonitis (SBP) is infection of cirrhosis-related ascites. It may cause a florid sepsis syndrome with shock and renal failure, or have an onset that is insidious and detected only at paracentesis. Pyrexia, changes in mental state and abdominal tenderness are common. Routine paracentesis demonstrates an incidence of SBP of up to 27% at the time of hospital admission.[40] Mortality rates for patients surviving their first hospital admission are 70% at 1 year, and 80% at 2 years. Prolonged bacteraemia, immune paresis and intrahepatic shunting probably play a role in the aetiology of SBP.

The bacterial concentration in ascitic fluid tends to be comparatively low and so 10–20 mL of ascitic fluid are introduced into blood culture bottles at the bedside to increase the diagnostic yield.

It is extremely important, in terms of management, to differentiate SBP from secondary peritonitis. The mortality rate of SBP approaches 100% if appropriate surgical intervention is omitted. However, the mortality rate is about 80% if a patient with SBP receives an

Box 44.2.2 Diagnostic criteria for HRS

- Cirrhosis with ascites
- Creatinine >1.5 mg/dL
- No improvement in serum creatinine (>1.5) after 2 days of diuretic withdrawal and volume expansion with albumin (1 g/kg/day up to 100 g/day)
- Absence of shock
- No nephrotoxins
- Absence of parenchymal kidney disease (proteinuria >500 mg/day, microhaematuria >50 red blood cells per high-power field) and/or abnormal renal ultrasound

unnecessary exploratory laparotomy.[41] Culture in SBP tends to reveal a single responsible pathogen.

There has been an emergence of enterobacteria strains harbouring ESBLs or beta lactamases which are able to hydrolyse cephalosporins and broad-spectrum penicillins and other resistant bacteria, such as *Pseudomonas aeruginosa*, methicillin-resistant *Staphylococcus aureus* (MRSA) and *Enterococcus faecium*. Predispositions for the acquisition of multi-resistant organisms include hospitalisation, antibiotic exposure and norfloxacin prophylaxis. Authors have suggested that quinolones should be avoided in the treatment of SBP or any other infection in patients on long-term norfloxacin prophylaxis.[42]

RENAL FAILURE IN CHRONIC LIVER DISEASE

Renal failure occurs in 27% of septic cirrhotics in the absence of SBP and in 33% with SBP.[43] Hepatorenal syndrome (HRS) is a prerenal failure that does not respond to fluid therapy. The diagnostic criteria are listed in **Box 44.2.2**.[44]

There is an association with renal/splanchnic insufficiency. Infections, bleeding and large-volume paracentesis without adequate volume replacement are common precipitating factors. Type 1 HRS progresses rapidly, and often occurs in the setting of haemodynamic compromise. Type 2 HRS is said to be characterised by a slowly progressive deterioration in renal indices and is frequently associated with ascites. HRS is associated with a diminished survival probability (**Fig. 44.2.2**).

Ischaemic acute tubular necrosis (ATN) is common in patients with acute or chronic liver failure who develop SIRS/sepsis. The administration of 20% albumin was associated with a reduction in the incidence of renal failure and of mortality.[45] Terlipressin may also have a role in the treatment of hepatorenal syndrome.[46,47] More recent data suggests that norepinephrine may be equally applied.[48-51]

Ascitic drainage should be undertaken with appropriate albumin loading if large-volume drainage is undertaken or in patients at risk of central volume depletion.[52]

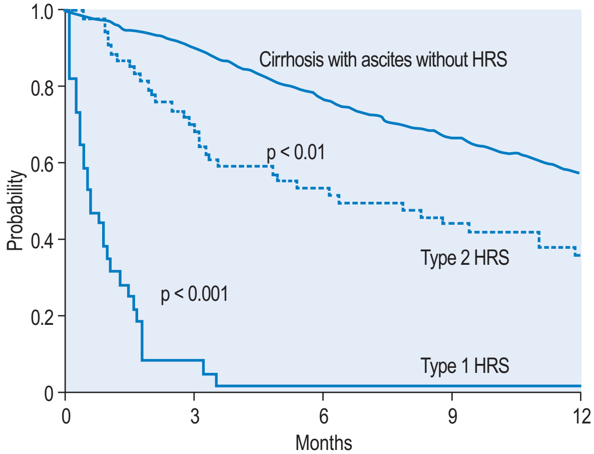

Figure 44.2.2 Actuarial survival probability in cirrhotic patients with HRS. *(From: Salerno F, Gerbes A, Gines P, et al. Diagnosis, prevention and treatment of hepatorenal syndrome in cirrhosis. Gut 2007;56:1310–8, with permission.)*[44]

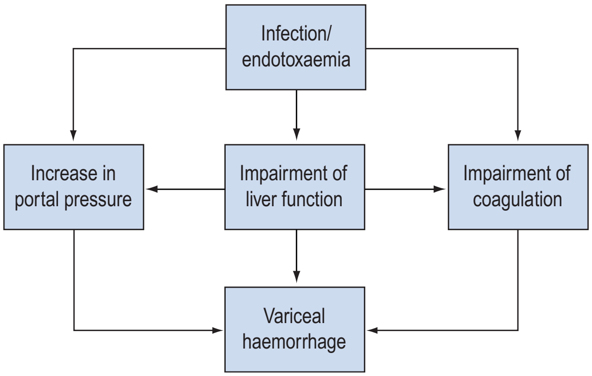

Figure 44.2.3 Pathophysiology of variceal bleeding in ACLF. *(From Thalheimer U, Triantos CK, Samonakis DN, et al. Gut 2005;54:556–63, with permission.)*[12]

VARICEAL BLEEDING IN CHRONIC LIVER DISEASE

The development of infection in cirrhosis is associated with a failure to control variceal bleeding and with early variceal re-bleeding. The incidence of sepsis is also higher in patients with uncontrolled bleeding (**Fig. 44.2.3**).

Propanolol, which is used to lower portal pressures following variceal haemorrhage, was shown to lower incidence of infection from 42% to 15% in a cohort of 73 cirrhotics.[53] It is not clear whether this effect is attributable to increased gut motility, and thus reduced bacterial translocation.

Infection may predispose to variceal bleeding because of an elevation in sinusoidal pressure – and hence portal pressure – and a worsening of

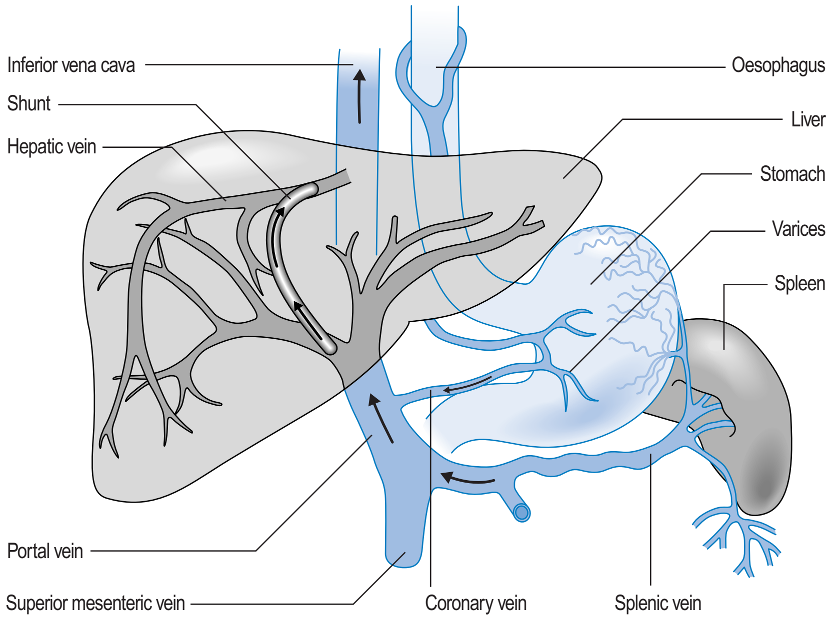

Figure 44.2.4 Transjugular intrahepatic portal systemic shunt.

coagulopathy. NO synthesis (the circulating form is *S*-nitrosothiol) attenuates platelet aggregation and heparinoid synthesis by endothelial cells increases.

It is recommended that patients with bleeding complications be treated with antibiotics.[54] The management of variceal haemorrhage remains that of basic resuscitation and care of the airway. Coagulation factors require appropriate supplementation along with other blood products. Cultures should be taken and all patients with variceal haemorrhage should be given antibiotics and this has been shown to decrease the risk of rebleeding.[55,56] Splanchnic vasoconstrictors, such as terlipressin, are beneficial in controlling oesophageal haemorrhage but their role in gastric variceal haemorrhage per se has not been examined.[48,57] Banding ligation therapy remains the treatment of choice for oesophageal haemorrhage, with tissue adhesives being utilised in gastric varices.

Failure to control variceal bleeding after two endoscopic sessions should result in consideration of TIPS insertion.[58,59] In patients in whom TIPS (**Fig. 44.2.4**) might be considered to be of benefit in controlling variceal bleeding, consideration needs to be given to the severity of the underlying liver disease that may in its own right make TIPS ill-advised.[60]

CARDIORESPIRATORY FAILURE

Cirrhotics display altered haemodynamics at baseline, with a hyperkinetic, vasodilated circulation. Patients tend to be tachycardic and hypotensive, with high cardiac output and low peripheral vascular resistance. Despite this, cirrhotic patients may have markedly abnormal tissue oxygenation, with arteriovenous O_2 content difference and O_2 uptake.[61] These changes become more profound with the onset of the septic state. Fluid resuscitation is complex, and probably best guided by the use of a cardiac output monitor. Patients may not respond to vasopressors as vigorously as the non-cirrhotic septic cohort. Left ventricular dilatation and dysfunction may be apparent on echocardiography.

Respiratory failure is common in the cirrhotic cohort. Intubation is often required for airway protection in encephalopathy. Ventilator-associated pneumonia is common. Alveolar macrophage activity may be diminished.

Tense ascites inhibits diaphragmatic descent and predisposes to basal atelectasis/collapse. There may be an accumulation of fluid owing to increased capillary membrane permeability and exacerbated by attempts to resuscitate a relatively vasoplegic circulation.

There is a relatively high incidence of ARDS in cirrhosis. Mortality rates in ventilated cirrhotics are high.

DECOMPENSATIONS IN LIVER FUNCTION DURING THE SEPTIC EPISODE

Sepsis has the potential to worsen liver function, particularly in chronic cirrhotics. Acute on chronic liver failure has been defined as 'a syndrome characterised by the acute deterioration of liver function in a patient with compensated or decompensated, but hitherto stable cirrhosis. It is commonly precipitated by an acute event/precipitating factor and associated with failure in the function of extra-hepatic organs' (European Association for the Study of Liver failure, EASL). The mechanisms underlying decrements in liver function are likely to be multifactorial.

As outlined above, levels of pro-inflammatory cytokines are increased in many forms of chronic liver

Box 44.2.3 The Child-Pugh classification is a means of assessing the severity of liver cirrhosis

Score	Bilirubin (micromol/l)	Albumin (g/l)	PT (s prolonged)	Encephalopathy	Ascites
1	<34	>35	<4	None	None
2	34–50	28–35	4–6	Mild	Mild
3	>50	<28	>6	Marked	Marked

If there is primary biliary cirrhosis or sclerosing cholangitis then bilirubin is classified as <68=1; 68–170=2; >170=3.
The individual scores are summed and then grouped as:

- <7 = A
- 7–9 = B
- >9 = C

disease. It is now believed that Kupffer cell induction by bacterial cell wall products may mediate hepatic inflammation. Hepatic stellate cells (HSCs), the main fibrogenic cells in the liver, are also mediators of inflammation, regulating leucocyte trafficking and activation.[62] Activation of HSCs by LPS has been proposed as a potential direct link between inflammation and hepatic fibrosis. Activation of the stellate cell to a myofibroblast-like phenotype allows the production of fibrillar collagens and other matrix proteins that characterise the fibrotic response.[63]

There is a large body of evidence to support the role of endotoxin and LPS derived from Gram-negative bacteria in the development of hepatic inflammation. Alcohol exposure (acute and chronic) increases gut permeability to LPS, resulting in increased LPS serum levels.[62] Injury to the liver may be attenuated by selective digestive decontamination and by colectomy whereas the addition of LPS may augment liver injury caused by alcohol.[64]

What is, perhaps, unclear are the relative roles that Gram-negative and Gram-positive bacteria play in the pathogenesis of sepsis-related liver injury. There may be synergy between the TLR-2 and TLR-4 mediated pathways.[63]

COAGULOPATHY

The liver is responsible for the synthesis of the zymogens of both pro- and anti-coagulant factors. Cirrhosis is associated with a relative deficiency of the procoagulant factors II, V VII and X and anticoagulant factors protein C, protein S and antithrombin. Cirrhotic patients with severe sepsis have relatively lower levels of zymogen forms of clotting factors when compared with cirrhotic patients with infection (but not severe sepsis) and uninfected cirrhotics. Decreased zymogen levels are independently correlated with an elevated Child–Pugh score (Box 44.2.3) and are associated with significant increases in the relative risk ratios of in-hospital death.[65] Thrombocytopenia is secondary to hypersplenism and becomes more profound in sepsis.

ACUTE ALCOHOLIC HEPATITIS

Alcoholic hepatitis is a frequent cause of decompensation and requires aggressive treatment. The severity can be assessed using the Glasgow score or Madrey score and in high-risk patients steroid therapy may be considered.[66,67] Response to steroids over the first 7 days is associated with improved outcome.[68] The role of antioxidants has been examined but no benefit was seen.[69,70] Another approach has been to look at the value of enteral feeding, which was comparable with steroid treatment over a 4-week period, albeit in a small study.[71] The use of pentoxifylline has been reported in a single-centre study to decrease the risk of developing hepatorenal failure and hence impacting on outcome.[72]

Abdominal surgical catastrophes

Stephen J Streat

Intra-abdominal surgical catastrophes are common in intensive care units,[1] typically occurring in older patients with co-morbidity and reduced physiological reserve.[2] They are often associated with sepsis (primarily or secondarily), multiple organ failure, multiple surgical procedures and prolonged intensive care stay. Mortality is high[2,3] both within ICUs and afterwards, post-ICU hospital length of stay is often very long and there is both increased post-hospital mortality and reduced functional status[4,5] particularly if severe co-morbidity and functional impairment were previously present.

These factors necessitate treating clinicians to reconsider carefully and frequently the costs and benefits[6,7] of treatment during an illness that often has the character of a tragic saga.[8] The clinical issues alone are complex and decisions must often be made without the benefit of controlled trials of various strategic approaches. These difficulties create the potential for conflict to arise between intensivists and other involved clinicians, particularly surgeons whose relationship with the patient may reflect a different 'moral economy'[8] and who may have different views of what constitutes realistic goals and reasonable strategies[9] for patients who are often near the end of life.[10,11] It is in the care of these patients that the particular day-to-day work skills of the intensivist[12,13] ('seeing the big picture', providing meticulous bedside care, negotiating and maintaining consensus, facilitating communication and cooperation between clinicians and the family) are tested to the limits. Vascular catastrophes, intra-abdominal sepsis and a few serious abdominal complications are discussed in this chapter; gastrointestinal bleeding and pancreatitis are covered elsewhere (Chs 42 and 43).

VASCULAR CATASTROPHES

ABDOMINAL AORTIC ANEURYSM

Abdominal aortic aneurysm (AAA) is a disease of the elderly, and up to six times more common in men than women.[14] Rupture of an abdominal aortic aneurysm is the most common vascular catastrophe seen in ICUs and accounts for 2% of all deaths in men over 60 years of age.[15] The prevalence of AAA, defined as infrarenal aortic diameter of 30 mm or more, as detected by screening in men, rises from less than 1% at age 50 to around 4% at aged 60, 5–10% at age 70 and around 10% at age 80. Ultrasound screening of elderly men for AAA reduces mortality and is probably cost-effective,[16] but in the Western world as smoking declines this may not remain the case.[17]

Aortic diameter is the strongest predictor of the risk of rupture, which is below 1% per year with aortic diameter <5 cm and about 17% per year with aortic diameter of 6 cm or more.[15] The risk of rupture is higher in women (who have faster aneurysm growth rates than men[18]) and is increased by current smoking and hypertension. Aortic aneurysm expansion is around 0.3 cm per year for aneurysms smaller than 5 cm and around 0.5 cm per year for those larger than 5 cm and this rate may be able to be reduced by a short course of macrolide or by stopping smoking. Perioperative mortality for open elective aneurysm repair has fallen to ~3%[19] (higher when there is significant preoperative respiratory or renal dysfunction[20]) and endovascular repair has rapidly overtaken open repair[21] because of lower perioperative mortality (0.5%[19]). A slight mortality benefit for endovascular repair persists for 2–3 years, but after this there is a 'catch-up' in mortality and other complications including rupture after endovascular treatment with associated increase in cost.[22] Endovascular repair does not improve survival in patients judged medically unfit for open repair.[23,24] Operative mortality is increased to around 15% in urgently repaired (non-ruptured) aneurysms[25] and around 40% in ruptured aneurysms repaired as an emergency.[26] Endovascular repair of ruptured aneurysms is associated with lower perioperative mortality (e.g. 24% vs 44% in a non-randomised study[27]).

Ruptured aneurysm may lead to death before hospital admission in around 30% of cases,[28] is almost always lethal without repair[29] and not all patients are offered repair. These results have led to recommendations for population screening by ultrasound at age 65, continued surveillance for small aneurysms[30] and elective repair in patients without severe co-morbidity when aneurysm diameter exceeds 5 or 6 cm.[31,32]

RUPTURE OF AN ABDOMINAL AORTIC (OR ILIAC ARTERY) ANEURYSM

The clinical features of rupture include the sudden onset of shock and back pain or abdominal pain or

tenderness in a patient typically over the age of 70. Most ruptures are, at least initially, retroperitoneal with intraperitoneal rupture resulting in greater physiological disturbance and much higher subsequent operative mortality.[33] The correct clinical diagnosis is often not made by the first attending doctor[34] as a pulsatile abdominal mass is commonly not detectable[33] and many patients do not have shock when first seen. Although immediate bedside ultrasound may sometimes be able to confirm the clinical diagnosis without increasing delay, others have found that this investigation commonly delayed vascular surgical referral and subsequent operation without diagnostic benefit.[35] The diagnosis of ruptured aneurysm is confirmed (by CT angiography) in only half of the patients in whom it is suspected,[36] but CT comes with risk of sudden deterioration outside the operating room. It is sometimes inappropriate to proceed to repair (very severe co-morbidity, poor quality of life) and this decision should be very carefully considered.[37] Lack of physiological reserve (often associated with advanced age) predicts high operative mortality and long periods of intensive care and hospitalisation in survivors. Open repair is commonly offered, but endovascular repair is increasingly advocated[38] although randomised trial evidence of superiority is not yet available.[36,39,40] A very small number of patients with aortic aneurysm have infection of the aneurysm, usually with *Staphylococcus* or *Salmonella*, which is often diagnosed at rupture.[41]

A period of intensive care after aneurysm repair is appropriate for most patients. During this time, common physiological abnormalities (e.g. hypothermia, dilutional coagulopathy, minor bleeding, circulatory shock, renal tubular dysfunction) can be corrected and serious complications can be sought and if possible treated (e.g. major bleeding, renal failure, myocardial infarction, acute lung injury, peripheral ischaemia, stroke, pulmonary embolism, persistent ileus, mesenteric ischaemia, pancreatitis, acalculous cholecystitis, increased intra-abdominal pressure). Rapid ventilator weaning and extubation is recommended, perhaps with thoracic epidural anaesthesia[42] if coagulation allows. Abdominal decompression in these particular patients may not be helpful.[43] Finally, an assessment of overall progress should be made after 24–48 hours. Severe or progressive multiple organ failure[44] or major visceral or limb infarction should lead to a reappraisal of the appropriateness of continued intensive therapies. Persistent renal failure occurs more commonly after acute renal failure in this context than in other intensive care patients. Massive upper gastrointestinal haemorrhage (usually aorto-duodenal) is a rare complication usually resulting from infection of a previous aortic repair and less commonly from primary infection in an aortic aneurysm. Some of these patients can be rescued surgically.

ACUTE AORTIC OCCLUSION

This is an uncommon syndrome and is usually due to thrombotic occlusion (of a stenotic or aneurysmal aorta) or to saddle embolism that presents with painful lower limb paraparesis or paraplegia and absent distal circulation. Minimising delay to emergency revascularisation is of the essence, but mortality and multi-system morbidity remain high.[45,46]

MESENTERIC INFARCTION

This uncommon syndrome presents with an acute abdomen, may develop in critically patients and is commonly due to non-occlusive arterial ischaemia, arterial embolism or atherosclerotic arterial thrombosis and less often to venous occlusion, low-flow or hypercoagulable states.[47] Recently reported outcomes have improved[48] with a coordinated multidisciplinary approach including endovascular revascularisation,[49,50] surgery (often including gut resection) and intensive care.

AORTIC DISSECTION

Aortic dissection[51] has an incidence of 5–30 per million per year. The typical patient is elderly, has a history of hypertension[52] and presents with pain in a distribution corresponding to the site of dissection. Cases have been reported in young people and after circumstances suggesting acute situational hypertension. Pericardial tamponade, haemothorax, myocardial infarction, stroke, paraplegia due to spinal cord ischaemia, anuria or an acute abdomen may be present. Most aortic dissections originate in the ascending thoracic aorta. Some dissections extend to involve the abdominal aorta, but spontaneous dissection of the abdominal aorta alone is rare. Mortality remains high but is falling in association with earlier diagnosis and treatment,[51] which now most commonly involves endovascular repair for uncomplicated abdominal aortic dissection.[53–55]

SPONTANEOUS RETROPERITONEAL HAEMORRHAGE

Spontaneous retroperitoneal haemorrhage (excluding aortic aneurysm rupture) is uncommon and usually associated with anticoagulant therapy, including warfarin, unfractionated heparin, low-molecular-weight heparin and antiplatelet agents,[56] or with vascular or malignant disease of the kidney or adrenal gland and less commonly with spontaneous rupture of the retroperitoneal veins. The presentation is most often with acute abdominal pain, shock and a palpable abdominal or groin mass, and CT will confirm the diagnosis.[57] Transfusion, correction of coagulopathy and interventional radiological embolisation may control some situations but surgery may be required in others, either to stop bleeding or to relieve associated intra-abdominal hypertension.

INTRA-ABDOMINAL SEPSIS

Intra-abdominal sepsis is very common in the ICU. In our own experience the abdomen (including CAPD peritonitis) was the most common septic site in patients admitted to ICU with severe sepsis and accounted for 404 (35.9%) of the 1131 such admissions over the 9 years 2000–2008.[58] Only 11% of these patients with intra-abdominal sepsis died in ICU but higher mortality is commonly reported for such patients, depending on the extent of co-morbidity[59] and the severity of the acute illness.

The general principles of the treatment of severe sepsis are to support oxygen transport with ventilator support, fluid therapy and inotropic support, to diagnose and if possible remove the septic source[60,61] and to give appropriate antimicrobial therapy.[62] Sepsis should be thought of as a time-critical condition[62] wherein delay in the execution of these principles is likely to worsen outcome. A clear role for other therapies is not yet established.[62] The issue of severe sepsis in general is covered in Chapter 69. In the critically ill patient with intra-abdominal sepsis, effective source control usually involves surgery although occasionally interventional procedures may suffice. Laparotomy is recommended (without delay or further investigation) for most patients presenting acutely with shock and clinical evidence of peritonitis. Diagnostic peritoneal aspiration or lavage, ultrasonography, CT scanning or laparoscopy may have limited applicability in some circumstances.

Common syndromes[63] include:

- faecal peritonitis
- primarily – diverticular disease or colonic malignancy
- secondarily – after prior anterior resection
- perforated upper abdominal viscus (usually of a gastric or duodenal ulcer)
- biliary obstruction (sometimes with perforation)
- intestinal infarction without perforation (usually adhesive, less commonly ischaemic)
- appendicitis (often perforated in older patients).

Less common syndromes include localised intra-abdominal abscess, acalculous cholecystitis, toxic megacolon, perforation of a fallopian tube abscess, spontaneous bacterial peritonitis (in end-stage liver disease or nephrotic syndrome) and CAPD-associated peritonitis (some of which is surgical).

SURGICAL SOURCE CONTROL

Surgical source control should remove the septic focus at the first ('damage control') operation, but definitive surgery may not be feasible or desirable at this time. Initial surgery[60] involves:

- removal of all peritoneal contamination (both macroscopically and by generous lavage)
- drainage of abscesses
- resection of devitalised tissue
- defunctioning of the gut (diverting the enteric stream) to prevent ongoing contamination.

The abdomen may be left open (with a temporary fascial closure) if required for intra-abdominal hypertension or to facilitate repeat laparotomy. Successful primary colonic anastomosis (even left-sided) after resection in the presence of sepsis is supported by evidence from case series[60,64] and a recent small randomised controlled trial.[65]

Failure of the sepsis syndrome to settle ('failure to thrive') after apparently definitive surgical source control should suggest ongoing contamination or ischaemia or the development of abscess. Repeat laparotomy on clinical grounds is recommended when early postoperative progress is unsatisfactory,[3] as CT performs poorly in this situation,[66] whereas CT scanning followed by either directed laparotomy[67] or interventional radiological drainage is a more successful strategy for late abscess formation.

INTESTINAL-SOURCE PERITONITIS

Peritonitis secondary to contamination by intestinal contents usually results in mixed aerobic and anaerobic infection. Recommended antibiotic regimens[58,61,68] are based on a paucity of randomised controlled trial evidence and usually involve either monotherapy with a carbapenem (or piperacillin–tazobactam) or combination therapy with a third- or fourth-generation cephalosporin and metronidazole. An aminoglycoside is often recommended in addition where the risk of resistant Gram-negative bacteria is particularly high.[61] Similar antibiotic regimens are appropriate in sepsis following intestinal infarction without perforation. An agent active against *Staphylococcus aureus*[69] should be considered in patients with peritonitis following gastric or duodenal perforation.

BILIARY SEPSIS

Biliary ultrasound followed by endoscopic sphincterotomy and stone removal is recommended for critically ill patients with cholangitis. Antibiotic regimens should cover enterococci and aerobic Gram-negative bacilli.

ACALCULOUS CHOLECYSTITIS

Acalculous cholecystitis is a rare but serious condition in intensive care units. A small number of patients with the syndrome of acute cholecystitis will have acalculous cholecystitis, but these patients have low mortality and do not present to intensive care units. Of greater concern are the perhaps half of all cases of acalculous cholecystitis that develop insidiously in intensive care patients already critically ill for another reason (e.g. recent trauma or surgery) and can therefore go unrecognised until gangrene, perforation or abscess develop. The gallbladder histology in such patients usually includes prominent ischaemia and arteriosclerosis and low cardiac output may predispose to the condition. There should be a high index of suspicion in an

intensive care patient who develops new abdominal pain or clinical signs of sepsis. Although a variety of investigations including scintigraphy, CT scanning, ultrasound and laparoscopy[70] have been used to help establish the diagnosis, none perform reliably[71] and many surgeons advocate a low threshold to exploratory laparotomy on clinical grounds where suspicion exists. Percutaneous cholecystostomy[60] has been used successfully, whereas early cholecystectomy is advocated by others[72] as infarction or perforation of the gallbladder is commonly found at laparotomy.

TOXIC MEGACOLON

Toxic megacolon[73] is now a rare indication for intensive care admission. It is characterised by systemic toxicity accompanying a dilated, inflamed colon and is usually due to inflammatory bowel disease. Infection by *Clostridium difficile*, cytomegalovirus (in patients with HIV disease or immunosuppression) or rarely other organisms may also precipitate toxic megacolon. The diagnosis should be considered in patients with diarrhoea and abdominal distension. Limited colonoscopy (despite the risk of perforation) and biopsy may both yield important microbiological information and help in the decision to operate. Supportive therapy in an intensive care unit is usually recommended and includes both antibiotics as for colonic perforation and steroids (equivalent of ~300 mg/day of hydrocortisone). Other immunosuppression (with calcineurin inhibitors or anti-TNF monoclonal antibody) has also been used. Frequent surgical reassessment and abdominal X-rays are used to monitor progress. Intravenous nutrition may help to reduce the activity of Crohn's disease but does not reduce hospital stay or the need for surgery in ulcerative colitis. A period of several days of careful observation may be reasonable to assess the response to medical treatment but urgent surgery (subtotal colectomy with end-ileostomy) is indicated for increasing colonic dilatation, perforation, bleeding or progressive systemic toxicity.[74] Parenteral metronidazole may be effective in severe pseudomembranous colitis without megacolon (but early surgery is often recommended if megacolon develops).

RUPTURE OF A TUBO-OVARIAN ABSCESS

Rupture of a tubo-ovarian abscess is a rare cause of peritonitis presenting to intensive care units and is best treated with surgical extirpation. Antibiotic therapy should including activity against anaerobic organisms.

SPONTANEOUS BACTERIAL PERITONITIS

Spontaneous bacterial peritonitis (SBP) is usually a monomicrobial infection (usually with *Escherichia coli*, *Klebsiella pneumoniae*, pneumococci or enterococci and rarely with anaerobes).[58] The development of SBP in patients with end-stage liver disease is often followed by hepatic decompensation and multiple organ failure (see Ch. 44). Those who recover are at high risk of death without liver transplantation. Early albumin supplementation has been shown to reduce both renal failure and mortality in SBP associated with end-stage liver disease.[75] Treatment with a broad-spectrum beta-lactam antibiotic should be followed by secondary oral antibiotic prophylaxis.

CAPD-ASSOCIATED PERITONITIS

Peritonitis in CAPD patients rarely necessitates intensive care admission and such patients should be assessed for abscess formation, the presence of unusual organisms including fungi or an unrecognised gastrointestinal septic source.[76]

TERTIARY PERITONITIS

Tertiary peritonitis ('peritonitis in the critically ill patient that persists or recurs at least 48 hours after the apparently adequate management of primary or secondary peritonitis'[77]) occurs occasionally in severely ill patients with prior laparotomy. It is commonly due to *Pseudomonas aeruginosa*, *Staphylococcus epidermidis*, *Enterococcus* spp., *Enterobacter* spp., resistant *Bacteroides* or *Candida* spp.[58,61,77] and antimicrobial treatment should reflect these organisms until guided by cultures. When infection is due to *Candida* spp. other antimicrobial agents should be discontinued, any foreign bodies removed if possible, and treatment with amphotericin B given for at least 4 weeks.[78]

COMPLICATIONS

INTRA-ABDOMINAL HYPERTENSION AND THE ABDOMINAL COMPARTMENT SYNDROME

These phenomena occur uncommonly in critically ill patients, particularly after laparotomy for trauma or sepsis and in association with obesity[79] and excessive fluid administration. Intra-abdominal hypertension has been defined as intra-abdominal pressure (IAP) >12 mmHg (1.6 kPa) and abdominal compartment syndrome as IAP>20 mmHg (2.66 kPa) with associated organ dysfunction.[80] Intra-abdominal pressure (IAP) can be conveniently and easily measured via intravesical pressure,[43,80] is normally 5–7 mmHg (0.66–0.93 kPa) in critically ill adults and is increased in patients with increased body mass index. Physiological impairment (including cardiorespiratory, renal, splanchnic, and neurological) can occur with acute increases in IAP to levels above 12 mmHg. However, in the absence of evidence from randomised controlled trials, expert opinion[81] suggests that the development of the abdominal compartment syndrome (IAP>20 mmHg with associated organ dysfunction) should prompt a search for decompressive measures. Traditionally this has involved urgent decompressive laparotomy and

temporary fascial closure; however, other measures (avoidance of the prone position, gastric and colonic decompression, neostigmine or other prokinetic agents, neuromuscular blockade, diuresis or ultrafiltration, percutaneous drainage of intraperitoneal fluid or gas) may be effective in some patients and should also be considered.[81] Mortality for such patients is probably falling with early use of decompression but remains high (~25%).[82]

THE OPEN ABDOMEN AND STAGED ABDOMINAL REPAIR

The use of synthetic materials to provide temporary fascial closure or of a negative-pressure wound technique over porous materials (sponge or towels) has facilitated the care of the patient with an open abdomen and allowed repeat laparotomy and staged abdominal repair to proceed in a timely and unhurried manner.[83] Our own practice[43] used to involve the use of polypropylene mesh for fascial closure if the abdomen was to be open for a short time (less than a week) to remove it before significant adhesion occurred. Alternatively a negative-pressure wound dressing[84] over a porous material (sponge or towels) can also achieve the necessary objectives of decompression, ascites removal and prevention of evisceration. Care should be taken to prevent adherence of any material placed over the abdominal contents to minimise the risk of gut perforation and fistula during removal of the material and eventual wound closure. The management of fistulation in the open abdomen remains problematic as proximal defunctioning is often impossible and better control of wound contamination is probably achieved with a negative-pressure wound care system rather than with soft-catheter intubation of the small bowel via the fistulous tract.

ENTEROCUTANEOUS FISTULAS – INTESTINAL, BILIARY AND PANCREATIC

These are rare complications in intensive care patients but they usually present formidable problems because of their common associations with serious gastrointestinal co-morbidity (e.g. inflammatory bowel disease, intestinal malignancy, pancreatitis) and concurrent severe sepsis. In addition, fistulation through an open abdomen, complex fistulation with multiple collections, inability to proximally defunction or distal intestinal obstruction are commonly present. A standard approach to fistula management should apply[85] including attention to drainage of sepsis, control of the fistula by drainage or if necessary by proximal defunctioning, protection of the skin from the deleterious effects of the fistula fluid, nutritional support and replacement of fluid and electrolyte losses.

Somatostatin analogues have been shown to reduce high-output small bowel fistula losses, probably enhance fistula closure[86] and may reduce the incidence of pancreatic fistula when used prophylactically in pancreatic surgery.[87] Parenteral nutrition is usually recommended for proximal small bowel fistulas but more distal intestinal, biliary or pancreatic fistulas can probably be safely treated with a trial of enteral nutrition. Treatment with an anti-TNF antibody has been shown to be effective in chronic enterocutaneous fistulas in (non-ICU) patients with Crohn's disease.[88,89] Persistent high-output fistula should lead to investigation of possible causes including complete disruption of the gut lumen, distal obstruction or persistent intra-abdominal sepsis. Definitive operative treatment for fistulas that do not close should await clinical recovery and if possible nutritional repletion.

COLONIC PSEUDO-OBSTRUCTION

Colonic pseudo-obstruction (Ogilvie's syndrome, a severe form of colonic ileus) is not uncommon in critically ill patients. The syndrome may contribute to ventilatory difficulty, intra-abdominal hypertension and failure of enteral feeding and carries a small risk of spontaneous perforation with high resultant mortality. Conventional conservative treatment includes nasogastric drainage, intravenous fluid replacement and avoidance of opioids and anticholinergic agents. Treatment with neostigmine has been found to be highly effective[90] but may cause symptomatic bradycardia and even cardiac arrest.[91]

Colonoscopy or surgery may be required if these measures fail.[92,93]

Solid tumours and their implications in the ICU

Timothy Wigmore and Pascale Gruber

The term 'solid tumour' refers to masses of tissue not containing cysts or liquid. There are over 200 types and they are classified according to the tissue of origin. Most arise from epithelial tissues and are termed carcinomas. They are further differentiated into squamous cell (which include tumours of skin, oropharynx, oesophagus, cervix and lung) and adeno- (which include those originating in lung, colon, breast, pancreas and stomach). Rarer tumours originate from connective tissue (sarcomas), the neuroectoderm (gliomas, glioblastomas, neuroblastomas, medulloblastomas) or germ cells (teratomas, seminomas and choriocarcinomas).

There were 12.7 million new cancer cases worldwide in 2008 and this number is expected to reach 26 million by 2030.[1] This increase is attributable to an ageing population and lifestyle changes, with diet, lack of physical activity and obesity all playing a role. The most common cancers worldwide are lung (12.7% of the total), breast (10.9%) and colorectal cancers (9.7%) whilst the commonest causes of cancer deaths are lung (18.2% of the total), stomach (9.7%) and liver cancer (9.2%).

This case-load presents a substantial challenge to intensive care physicians. In the SOAP (Sepsis Occurrence in Acutely Ill Patients) study[2] cancer patients accounted for 15% of all ICU admissions, 85% of which were solid tumours. The Intensive Care National Audit and Research Centre case-mix review of 128 adult general ICUs in the United Kingdom demonstrated that bowel and oesophageal tumours accounted for the fourth and eighth most common reasons for ICU admission respectively.[3]

Patients with solid cancers present to ICU either postoperatively, with complications of cancer treatment, as a result of the underlying cancer itself or with other co-morbidities unrelated to the cancer.

CANCER TREATMENTS

Cancer treatments fall broadly into the three main categories: chemotherapy, radiotherapy and surgery. Many patients have a combination of all three, and it is increasingly common for patients to receive neoadjuvant chemotherapy prior to surgery to facilitate surgical resection. Chemotherapeutic agents affect DNA synthesis, structure or repair and are usually unselective in that they affect all rapidly dividing cells. They may therefore also affect cells in the gut (with resulting mucositis and diarrhoea), bone marrow (leading to thrombocytopenia, anaemia and immunosuppression) and hair (causing alopecia). Additionally, many chemotherapeutic drugs have agent-specific side-effects that may have implications for ICU (see Table 46.1), for example anthracyclines- or trastuzumab-related cardiomyopathy, bleomycin-related lung injury or ifosfamide-induced encephalopathy.

Agents commonly used in combinations are represented by acronyms. Confusingly, the same agent may be represented by different letters depending on whether the generic or brand name has been used, and equally multiple agents may be represented by the same letter (**Table 46.1**).

SPECIFIC CHEMOTHERAPY-INDUCED TOXICITIES

BLEOMYCIN-RELATED LUNG INJURY

Bleomycin is an antibiotic derived from *Streptomyces* spp. that causes DNA scission through the generation of oxygen superoxide radicals. It is used for the treatment of head and neck squamous cell carcinomas, cancers of the cervix and germ cell tumours. It causes pneumonitis in up to 40% of patients, with subsequent mortality in up to 2%.[4] Toxicity is caused by the generation of oxygen free radicals with subsequent alveolitis and fibrosis. This is exacerbated by high oxygen concentrations.

IFOSFAMIDE NEUROTOXICITY

Ifosfamide is an alkylating agent used in the treatment of head and neck, cervical, ovarian, breast and lung cancers. It causes encephalopathy in between 10 and 30% of patients, with a severity ranging from mild confusion to coma. The diagnosis is essentially one of exclusion with normal brain imaging and an EEG demonstrating metabolic encephalopathy. The aetiology is thought to be related to direct toxicity from metabolites of ifosfamide, notably chloracetaldehyde or dicarboxylic acid. The incidence is greater in those with pre-existing low albumin, raised creatinine or with cisplatin pretreatment.[5] The natural history of the

Table 46.1 Examples of commonly used chemotherapy regimens

AC	Breast cancer	Adriamycin® (doxorubicin), cyclophosphamide
BEP	Germ cell tumours	Bleomycin, etoposide, cisplatin
CAV	Lung cancer	Cyclophosphamide, Adriamycin®(doxorubicin), vincristine
CEF	Breast cancer	Cyclophosphamide, epirubicin, fluorouracil,
FOLFOX	Colorectal tumours	Fluorouracil, folinic acid (leucovorin), oxaliplatin
FOLFIRI	Colorectal tumours	Fluorouracil, folinic acid (leucovorin), irinotecan
PCV	Brain tumours	Procarbazine, CCNU (lomustine), vincristine
VIP	Germ cell tumours	Ifosfamide, cisplatin, etoposide

encephalopathy is to regress over a period of days to weeks after cessation of ifosfamide. Methylene blue (50 mg 4-hourly intravenously) has been shown to ameliorate or even terminate symptoms.[6] (Proposed mechanism is inhibition of the conversion of chloroethylamine to toxic chloroacetaldehyde probably by inhibiting several different amine oxidases.)

ANTHRACYCLINE CARDIOMYOPATHY

Anthracylines, such as daunorubicin, doxorubicin and epirubucin, are widely used anticancer agents. Anthracyclines can cause both acute and chronic cardiac dysfunction. Acutely, 5% of patients suffer from arrhythmias or acute cardiac failure that resolves with standard treatment. Chronically, anthracyclines cause a dose-dependent cardiomyopathy that becomes apparent anywhere between 3 months and several years after treatment and can result in severe myocardial dysfunction. Initial treatment is with ACE inhibition, but the full range of medical therapies for heart failure may be required, including cardiac resynchronisation.[7]

TRASTUZUMAB (HERCEPTIN®) CARDIOTOXICITY

Trastumuzab may cause a non-dose-related, reversible myocardial dysfunction. This appears to involve an element of myocardial stunning rather than myocyte destruction. It is often asymptomatic but can cause symptoms of cardiac failure. Its occurrence does not preclude future dosing provided cardiac function has recovered prior to further use[8] (**Table 46.2**).

RADIOTHERAPY

Radiotherapy causes damage to cells through the production of oxygen free radicals by the ionisation of water molecules. These in turn cause damage to cellular DNA. Damage to healthy surrounding tissue is minimised by targeting the radiation beam through multiple planes that intersect within the tumour. Despite this, radiation commonly causes acute inflammation and subsequent fibrosis in the tissues through which it passes. Common examples are pericarditis, pericardial, myocardial and lung fibrosis. This can cause organ dysfunction, particularly when combined with a chemotherapeutic agent known to have toxicities associated with that same organ.

DISEASE-RELATED ADMISSIONS

A number of oncological emergencies can occur that require admission to ICU.

TUMOUR LYSIS SYNDROME (TLS)

Tumour lysis occasionally follows treatment for bulky solid tumours, particularly small-cell lung tumours, neuroblastomas and breast carcinomas.[9,10] The syndrome results from the rapid death of large numbers of tumour cells. This may occur spontaneously but usually follows chemotherapy, radiotherapy and occasionally surgery, with a consequent release of a high concentration of intracellular contents. This results in a constellation of metabolic abnormalities, specifically hyperuricaemia (and subsequent nephropathy due to deposition of uric acid crystals in the distal tubules), hyperkalaemia, hyperphosphataemia and hypocalcaemia (due to the precipitation of calcium phosphate). The priority with TLS is prevention, and patients with high- or intermediate-risk tumours should receive intravenous hydration and rasburicase (recombinant urate oxidase) as prophylaxis.[11] Rasburicase has generally replaced allopurinol as the agent of choice. Rasburicase catalyses the formation of water-soluble allantoin from uric acid, resulting in a rapid reduction in uric acid levels. In contrast, allopurinol prevents uric acid formation through the inhibition of xanthine oxidase, which results in a slower decrease in uric acid concentration and increases the concentrations of xanthine, which can result in xanthinuria – in itself a cause of renal failure.[12] Urinary alkinisation reduces the risk of uric acid precipitation by rendering it more water-soluble, but simultaneously increases the risk of calcium phosphate precipitation in the kidneys and other organs. Hyperkalaemia and hyperphosphataemia sometimes require renal replacement therapy.

SPINAL CORD COMPRESSION

Breast, prostate, lung and kidney cancers have a predilection for bony metastasis. High spinal cord

Table 46.2 Characteristic toxicities of commonly used chemotherapeutic agents

DRUG NAME OR GROUP	SOLID TUMOURS FOR WHICH TYPICALLY USED	MODE OF ACTION	CHARACTERISTIC TOXICITIES
Anthracyclines – doxorubicin, idarubicin	Breast, bladder, stomach, lung, ovary, thyroid	Intercalates DNA	Cardiotoxicity, 'hand-foot syndrome'
Alkylating agents – cyclophosphamide, ifosfamide	Many	Inhibits DNA replication	Immunosuppression, haemorrhagic cystitis, LV dysfunction, hyponatraemia
– ifosfamide	Ovarian, breast, lung, testicular		Neurotoxicity
– melphalan	Multiple myeloma, ovarian		Myelosuppression, interstitial pneumonitis
Bleomycin	Squamous cell, testicular	Induces DNA strand breaks	Pulmonary fibrosis
Cyproterone	Prostate	Inhibit tumour 'flare'	Hepatotoxicity
Fluorouracil	Colorectal, pancreatic	Thymidylate synthase inhibitor	Cardiotoxicity, neurodegeneration
Methotrexate	Choricarcinoma	Inhibits folic acid metabolism	Mucositis, pulmonary fibrosis, hepatitis, immunosuppression
Platinum analogues, e.g. carboplatin, cisplatin, oxaliplatin	Lymphoma, sarcoma, ovarian, small-cell lung	Selective inhibition of tumour DNA synthesis	Myelosuppression, nephro/oto/neurotoxicity, hypomagnesaemia with cisplatin
Procarbazine	Glioblastoma multiforme	Causes free radical formation	Myelosuppression, hypersensitivity rash
Monoclonal antibodies			
– Bevacizumab (Avastin®)	Colon, non-small-cell lung	Inhibits VEGF, inhibiting cell growth	Mucocutaneous bleeding, GI perforation
– Cetuximab	Colorectal, squamous cell, head and neck	Binds to EGFR, inhibits cell division	Severe hypersensitivity reactions
Trastuzumab (Herceptin®)	Breast	Binds HER2 receptor, inhibits cell division	Cardiotoxicity, hypersensitivity
Tamoxifen	Breast	Oestrogen receptor antagonist	Thrombosis, endometrial Ca, strokes
Taxanes, e.g. docetaxel, paclitaxel	Breast, prostate, non-small-cell lung	Impair mitosis	Cardiac conduction defects, peripheral neuropathy, hypersensitivity
Topoismerase inhibitors, e.g. irinotecan, topotecan	Colon	Inhibits DNA replication	Acute cholinergic syndrome
Vinca alkaloids – vincristine, vinblastine	Nephroblastoma	Inhibits assembly of microtubules arresting mitosis	Neuropathic ileus, peripheral neuropathy, hyponatraemia

VEGF=vascular endothelial growth factor; EGFR=epidermal growth factor receptor; HER2=human epidermal growth factor 2.

compression may require semi-urgent invasive mechanical ventilation. Treatment usually takes the form of steroids followed either by surgery or radiotherapy.

CARDIAC TAMPONADE

Pericardial effusions due to epicardial metastasis or mediastinal lymph drainage obstruction are relatively common with advanced lung and breast cancers.[13] Cardiac tamponade is less frequent and may develop with pericardial effusions as small as 200 mL if accumulated rapidly. On echocardiography, cardiac tamponade classically demonstrates right atrial or ventricular diastolic collapse, increase in right ventricular size or failure of inferior vena cava collapse on inspiration. The management of cardiac tamponade in the acute

setting is pericardiocentesis with subsequent pericardial window formation. For some tumours, treatment of the underlying cancer with chemotherapy and/or radiotherapy will result in longer-term resolution.

ELECTROLYTE DISORDERS

Rapid and life-threatening changes in electrolyte concentrations may result from paraneoplastic disorders, losses from treatment-induced diarrhoea or renal dysfunction. Paraneoplastic disorders result from the secretion of hormones or hormone-like substances from tumours. Syndrome of inappropriate antidiuretic hormone secretion (SIADH) typically occurs in the setting of small-cell lung carcinomas, which account for 80% of the total incidences of SIADH. SIADH also occurs with pancreatic, colonic, prostate, duodenal and head and neck tumours. It can be seen with cisplatin, ifosfamide, vincristine, vinblastine and cyclophosphamide use. Hyponatraemia is particularly marked when secondary to cyclophosphamide due to concurrent fluid loading to reduce the risk of haemorrhagic cystitis.[14] Chronic mild hyponatraemia ($Na+>125$ mmol/L) rarely requires intervention, whereas severe hyponatraemia ($Na+<125$ mmol/L) should be cautiously corrected to avoid osmotic demyelination.

Hypercalcaemia represents the most common metabolic consequence of solid tumours and occurs in 10–20% of patients.[15] The release of parathyroid-hormone-related peptides from lung, head and neck, kidney and pancreatic cancers, together with osteolytic calcium release from tumours with bony metastases (e.g. breast and prostate), can result in life-threatening hypercalcaemia. Treatment of hypercalcaemia is with a combination of saline rehydration, calcitonin and bisphosphonates (e.g. pamidronic acid (pamidronate)). Saline corrects hypercalcaemia-induced dehydration, calcitonin reduces resorption from bone by blocking osteoclast maturation and increasing renal calcium excretion, and bisphosphonates cause osteoclasts to apoptose.[16] The response to furosemide is variable and often requires the use of high doses resulting in electrolyte abnormalities, and is therefore not recommended.[17] The effect of bisphosphonates may be poor in those with parathyroid hormone related protein (PTHrP)-induced hypercalcaemia, although zoledronic acid may be useful.[18,19]

Hypokalaemia requiring admission to ICU is often the result of diarrhoea due to chemotherapy or radiotherapy. Hypokalaemia may also be caused by ACTH-producing lung tumours or from tumours that produce insulin.

Electrolyte disorders may be of sufficient severity to be life-threatening requiring immediate correction with intravenous replacement. They are also often accompanied by a normal anion gap hyperchloraemic metabolic acidosis caused by concomitant bicarbonate loss. This can result in marked acidaemia with consequent respiratory compensation that can lead to exhaustion in an already debilitated patient. It is best managed with bicarbonate replacement, although care needs to be taken to avoid worsening hypokalaemia.

SUPERIOR MEDIASTINAL SYNDROME

Patients with anterior mediastinal compression typically present to ICU either postoperatively or as an emergency with airway obstruction, cardiac compression or superior vena cava obstruction. The aetiology in adults is most commonly a thymoma, although lymphomas, germ cell tumours and sarcomas can also be responsible.[20] Airway obstruction may occur owing to compression of the trachea or bronchi. In an emergency there is often little time for formal assessment. Imaging may be available in the form of CT or MRI demonstrating the level and degree of compression. A decrease in cross-sectional area of 50% is predictive of airway complications.[21,22] If available, and symptoms permit, a CT scan can be conducted with the patient at 20–30 degrees of head-up, or in lateral or prone position to minimise airway compromise. Flow volume loops can demonstrate intrathoracic or extrathoracic airway obstruction although correlation with subsequent airway obstruction is variable.

Induction of anaesthesia may result in catastrophic airway obstruction due to a reduction in intrathoracic volume, increased size of (often very vascular) tumours with increased central blood volume, and increased compressibility of airways with reduction in smooth muscle tone. Equally, cardiovascular collapse may occur due to compression of the pulmonary arteries or superior vena cava. Should it be necessary to intubate the patient with superior mediastinal syndrome there are a number of key points that need to be considered.[23,24]

1. Establish venous access in the lower half of the body in case of superior vena caval obstruction, which would result in significantly slowed transit of administered drugs and fluids.
2. Have intravenous fluid administration established to minimise the effect of vascular obstruction.
3. In high-risk cases, establishment of femoral venovenous bypass under local anaesthesia prior to induction offers a route out in the event of complete airway obstruction. Having bypass on ‘standby’ is unlikely to be adequate due to the time required to establish it in the event of emergency.
4. Employ gaseous induction with preservation of spontaneous respiration or, if circumstances permit, an awake fibreoptic intubation to assess the degree of airway obstruction is advisable.
5. Neuromuscular blockade is best avoided. Subsequent positive-pressure ventilation (in concert with smooth muscle relaxation) may cause worsened bronchiolar obstruction leading to atelectasis and ventilation/perfusion mismatch. It will also increase

the pressure of the mass on mediastinal structures such as the superior vena cava, heart and pulmonary arteries with consequent potential cardiovascular collapse. If blockade is absolutely necessary, a trial of short-acting paralysis (e.g. with suxamethonium chloride (succinylcholine)) should be undertaken first. Should airway obstruction or cardiovascular collapse occur following intubation, repositioning the patient either sitting up, laterally or prone may be effective by reducing the mass effect. If this is ineffective and venovenous bypass is not possible, then emergency thoracotomy with manual displacement of the mass can be considered.

SUPERIOR VENA CAVA (SVC) COMPRESSION

SVC compression may be part of superior mediastinal syndrome but often occurs in isolation. When caused by tumour, the aetiology is normally lung cancer, lymphoma or a germ cell tumour.[25] The clinical presentation depends on the time period during which the compression has evolved as collaterals involving the azygos, internal mammary or oesophageal vessels develop over time and relieve the pressure. Patients typically present with facial and arm swelling, dyspnoea, cough and dysphagia. Those presenting to ICU are likely to have more immediately life-threatening features of either airway obstruction or cerebral oedema, in which case they may have stridor and a headache or a decreased level of consciousness.[26] In the absence of these features, SVC obstruction does not represent a true emergency and management should await histological diagnosis if one has yet to be made.[27] Endovascular stenting results in rapid resolution of symptoms in the vast majority of cases[28] and can be undertaken even in cases of complete obstruction. Radiotherapy is also effective in reducing tumour burden and achieving disease control in those cancers that are radiosensitive (which includes the majority responsible for SVC obstruction), but takes up to 4 weeks to take effect and can make subsequent histological diagnosis impossible. Steroids such as dexamethasone have a role in cases where the tumour is known to be steroid-sensitive (e.g. with lymphomas or thymomas) but are otherwise not indicated.[29]

NEUTROPENIA

Neutropenia is a common occurrence following the administration of chemotherapy and obviously predisposes the patient to infection. Care of the neutropenic patient in the intensive care setting is detailed in Chapter 99.

USE OF CHEMOTHERAPY IN THE ICU SETTING

There are little published data on the administration of chemotherapy for solid tumours in the ICU. Chemotherapy in ICU should be considered if its administration results in amelioration of life-threatening symptoms or a significant chance of improved patient outcome.[30] Prognostic indicators following chemotherapy administration appear to be similar to those for the general critically ill patient with cancer.[31]

THE EFFECT OF CRITICAL CARE ON CANCER

There has been little work looking into the effect of an ICU stay on tumour progression, but much of what happens to a patient during this period (be it disease- or treatment-mediated) has an impact on the function of the immune system and a potential consequent effect on tumour growth and metastases. The systemic inflammatory response syndrome associated with critical illness has been shown to decrease 5-year survival in patients with lung cancer.[32] Studies conducted in animals have shown that surgery in itself promotes metastasis. This is probably due to a combination of production of pro-inflammatory stimulators of tumour growth, the release of tumour cells directly into the circulation and the stress response. The stress response is mediated through the effect of catecholamines. Epinephrine (adrenaline) acts via β_2-receptors to decrease the number and activity of cytotoxic T and natural killer (NK) cells, both of which are known to destroy cancer cells. Norepinephrine (noradrenaline) has a similar effect, and has been found to induce the production of metastases in a rat model.[33,34] Interestingly, this effect was abolished by the administration of beta blockers. Tumours such as breast, colon and prostate seem to express β-receptors, which up-regulate growth when stimulated.

Hypoxia is tumour-simulating. Hypoxia leads to the production of cellular proliferative and angiogenic growth factors (notably vascular endothelial growth factor) via the generation of hypoxia-inducible factors 1α and 2α. The invasive mechanical ventilation that is commonly a response to hypoxia may similarly have a role to play; it results in the generation of immunomodulatory cytokines that add to the complex interplay of pro- and anti-inflammatory pathways.[35]

Blood transfusion can also increase the risk of tumour progression, particularly in the case of colorectal tumours. This is again thought to be related to immunosuppression. However, leucodepletion appears to make no difference to the impact on cancer recurrence after transfusion, and animal studies have suggested that transfusion of older blood may be implicated.[36]

Sedatives, induction agents and analgesics are also known to impact on cancer progression. Thiopentone, ketamine and propofol all decrease NK activity and numbers, with propofol having the least effect.[35] Morphine and fentanyl both decrease NK activity, and morphine has also been reported to promote angiogenesis and increase breast tumour cell growth in mice.[37]

In summary, admission to ICU for a patient with cancer carries a significant potential risk of promoting tumour growth and metastasis.

OUTCOMES FOR PATIENTS ADMITTED TO ICU WITH SOLID TUMOURS

The traditional view of the outcome for the critically ill cancer patient has been almost universally poor. However, for those with solid tumours, recent evidence has challenged and indeed overturned this view. Survival figures for those admitted to ICU have steadily improved over the past 15 years and approach those of patients admitted with non-oncological diagnoses in the most recent publications.[38,39,40] That said, the concept of considering all patients with solid tumours as a homogeneous group is probably flawed. A substantial proportion of the patients that present to ICU with an underlying diagnosis of solid tumour will be there for postoperative management. They have a similar mortality to patients admitted following any other major operative procedure. At the other extreme, patients with lung cancer admitted with a complication of disease or treatment have a completely different risk profile (and have an average medical ICU mortality of 36%).[41]

However, once in the ICU, prognostic indicators have, contrary to expectations, not shown disease progression, neutropenia or recent treatment with chemotherapy to be important. Instead, they are more related to the degree of acute physiological disturbance present at the time of presentation to ICU[39] and to the continued progression of organ dysfunction over the succeeding 72 hours after ICU admission. In this, the patients differ little from patients admitted to the ICU with a non-oncological diagnosis.

The reason for the improvements in reported survival of critically ill cancer patients are probably based around general improvements in ICU care including non-invasive ventilation and early goal-directed therapy, the existence of novel antitumour agents that are less cytotoxic and more efficacious, novel antifungal agents for the treatment of the neutropenic patient with fungal infection and better understanding of the management of oncological emergencies. Perhaps more importantly, there has been a change in attitude of intensive care physicians with more of us willing to admit and support critically ill cancer patients on the ICU.

Acute kidney injury

Rinaldo Bellomo

Acute kidney injury (AKI), formerly referred to as acute renal failure (ARF), is the new international consensus term for a condition that remains a major complication of critical illness and a therapeutic challenge for the intensivist. The term AKI has been introduced to emphasise a gradation of dysfunction and abnormality that begins long before 'failure' occurs.[1] In the ICU, AKI describes a syndrome characterised by a rapid (hours to days) decrease in the kidney's ability to eliminate waste products such as urea and creatinine. Other typical clinical manifestations include decreased urine output, metabolic acidosis and hyperkalaemia.

AKI can now be defined and classified using changes in serum creatinine and urine output using the so-called RIFLE criteria.[2] This classification uses the acronym of RIFLE, to divide AKI into the categories of Risk, Injury, Failure, Loss and ESKD (**Fig. 47.1**). Using this classification, the incidence of some degree of renal dysfunction has reported to be up to 67% in a recent study of >5000 ICU patients.[3] In a study of patients admitted to Australian and New Zealand (ANZ) ICU on day one, 36% of patients had a degree of AKI.[4] In hospital patients, the development of Failure (RIFLE classification) increases the odds ratio of death 10 times.[5] Later on another consensus definition was proposed by the AKIN (Acute Kidney Injury Network) group,[5] with minor modifications and, more recently, by the KDIGO consensus group.[6] Whatever the system of classification, however, the incidence of AKI appears to be increasing in ANZ ICUs (**Fig. 47.2**).

ASSESSMENT OF RENAL FUNCTION

Renal function is complex but, in the clinical context, monitoring of renal function is reduced to the indirect assessment of GFR by the measurement of urea and creatinine in blood. These waste products of nitrogen metabolism are insensitive markers of GFR and are heavily modified by many factors and by the administration of intravenous fluids.[7] Furthermore, they start becoming abnormal only after more than 50% of GFR is lost and do not reflect dynamic changes in GFR. The use of creatinine clearance (2- or 4-hour collections) or of calculated clearance by means of formulae rarely changes clinical management. The use of more sophisticated radionuclide-based tests is useful only for research purposes.

DIAGNOSIS AND CLINICAL CLASSIFICATION

The most practically useful approach to the aetiological diagnosis of AKI is to divide its causes according to the probable source of renal injury: prerenal, renal (parenchymal or intrinsic) or postrenal.

PRERENAL RENAL FAILURE

This form of AKI is by far the most common in ICU and is considered, at least in its initial phases, to be *functional* in nature. The term indicates that the kidney malfunctions predominantly because of systemic factors that decrease glomerular filtration rate (GFR) (i.e. decreased cardiac output, hypotension, sepsis and the like). If the systemic cause of AKI is rapidly removed or corrected, renal function improves and relatively rapidly returns to near normal levels. However, if intervention is delayed or unsuccessful, renal injury becomes established (*structural*) and several days or weeks are then necessary for recovery. Several urine tests (measurement of urinary sodium, fractional excretion of sodium and other derived indices) have been promoted to help clinicians identify the development of such 'established' AKI; unfortunately, their accuracy is doubtful.[8] Their clinical utility is low. Furthermore, prerenal ARF and established ARF are part of a continuum, and their separation has limited clinical implications.[9]

PARENCHYMAL (INTRINSIC) RENAL FAILURE

This term is used to define a syndrome where the principal source of damage is within the kidney and where *structural* changes can be seen on microscopy. Disorders that affect the glomeruli or tubules can be responsible (**Box 47.1**).

Among these, nephrotoxins are particularly important, especially in hospital patients. The most common nephrotoxic drugs affecting ICU patients are listed in **Box 47.2**. Many cases of drug-induced AKI rapidly improve upon removal of the offending agent. Accordingly, a careful history of drug administration is *mandatory* in all patients with ARF. In some cases of parenchymal AKI, a correct working diagnosis can be obtained from history, physical examination and radiological and laboratory investigations. In such

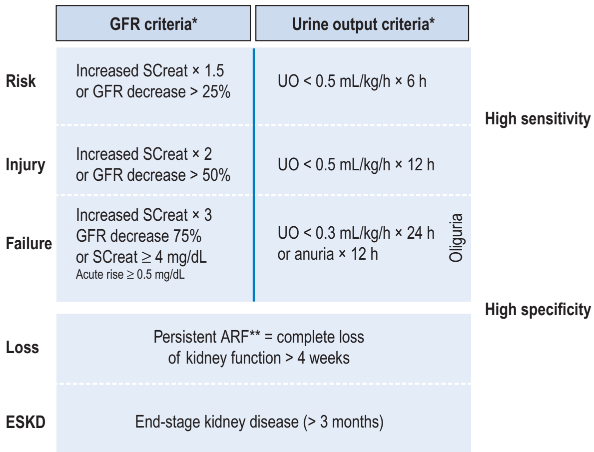

Figure 47.1 RIFLE (Risk Injury Failure Loss End stage) classification scheme for acute kidney injury. The classification system includes separate criteria for creatinine and urine output. The criteria, which lead to the worst possible classification should be used. Note that RIFLE-F (F=failure) is present even if the increase in serum creatinine concentration (S_{Creat}) is < threefold so long as the new S_{Creat}>4.0 mg/dL (350 µmol/L) in the setting of an acute increase of at least 0.5 mg/dL (44 µmol/L). The designation RIFLE-F_C should be used in this case to denote 'acute-on-chronic' disease. Similarly when RIFLE-F classification is reached by urine output criteria only, a designation of RIFLE-F_O should be used to denote oliguria. The shape of the figure denotes the fact that more patients (high sensitivity) will be included in the mild category, including some without actually having 'renal failure' (less specificity). In contrast, at the bottom, the criteria are strict and therefore specific, but some patients with renal dysfunction might be missed. GFR=glomerular filtration rate; ARF=acute renal failure; UO=urine output.

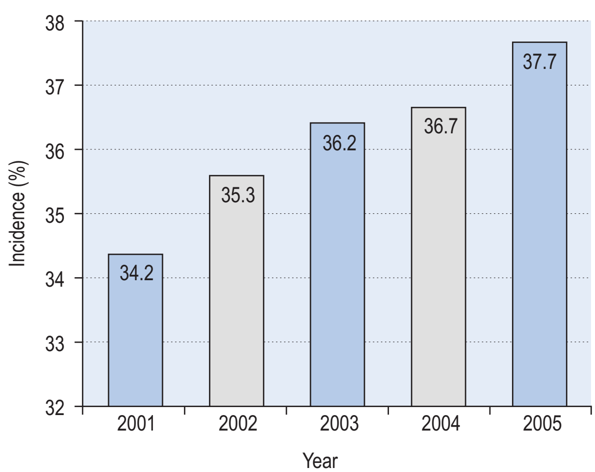

Figure 47.2 Graphic representation of the change in the incidence of AKI on day one after ICU admission in ICUs contributing to the adult patient database in Australia and New Zealand.

Box 47.1 Causes of intrinsic (parenchymal) AKI

- Glomerulonephritis
- Vasculitis
- Interstitial nephritis
- Malignant hypertension
- Pyelonephritis
- Bilateral cortical necrosis
- Amyloidosis
- Malignancy
- Nephrotoxins
- Cholesterol embolism

Box 47.2 Drugs that may contribute to AKI in the ICU

Radiocontrast agents
Aminoglycosides
Amphotericin
Non-steroidal anti-inflammatory drugs
β-lactam antibiotics (interstitial nephropathy)
Sulfonamides
Aciclovir (acyclovir)
Methotrexate
Cisplatin
Cyclosporin A
Tacrolimus
Sirolimus (rapamycin)
Starch solutions

patients one can proceed to a therapeutic trial without the need to resort to renal biopsy. However, if immunosuppressive therapy is considered, renal biopsy is recommended.

More than a third of patients who develop AKI in ICU have chronic renal dysfunction due to factors such as age-related changes, long-standing hypertension, diabetes or atheromatous disease of the renal vessels. Such chronic renal dysfunction may be manifest by a raised serum creatinine. However, this is not always the case. Often, what may seem to the clinician to be a relatively trivial insult that does not fully explain the onset of AKI in a normal patient is sufficient to unmask lack of renal functional reserve in another patient.

Beyond all the above considerations, however, the most common type of so-called intrinsic AKI falls under the traditional name of acute tubular necrosis (ATN). In classic teaching, ATN is used to describe a form of 'intrinsic' AKI that follows from severe and persistent prerenal AKI. It is assumed that tubular necrosis results from such continued hypoperfusion. This approach is widely accepted and used by textbooks and clinicians, but raises serious concerns.[10]

The first concern with the term ATN is that it conflates a histological diagnosis (tubular necrosis) that is rarely confirmed by biopsy (and is therefore not scientifically verifiable or falsifiable) with a complex clinical syndrome (typically AKI of >72 hours). Such a

syndrome, in many cases, has *not* been convincingly linked with the specific histopathological appearance of ATN in both animal experiments and human disease.[10]

The second concern is that ATN is believed to represent the consequence of sustained or severe prerenal azotaemia, which, unlike ATN, is believed not to be associated with histopathological changes (and is therefore not classified as intrinsic AKI). Such prerenal azotaemia can be expected to resolve over 2–3 days. Unfortunately, the term 'prerenal azotaemia' is, like ATN, conceptually flawed[11–12] because it implies that clinicians can know with a sufficient degree of certainty, by taking a history, examining the patient and performing urine and blood tests, that there is no histopathological injury to the tubules.

The third concern is that such concepts are biologically flawed because they imply that AKI does not represent (like all other known diseases) a continuum of injury but rather a yes-or-no phenomenon in terms of histological damage. For these reasons, terms like prerenal azotaemia and ATN are increasingly being challenged.[9,12]

HEPATORENAL SYNDROME (HRS)

This condition is a form of ARF that occurs in the setting of severe liver dysfunction in the absence of other known causes of ARF.[13] Typically, it presents as progressive oliguria with a very low urinary sodium concentration (<10 mmol/L). Its pathogenesis is not well understood. New consensus definitions, however, now define HRS as any development of AKI in the setting of advanced liver disease that is not due to intrinsic causes. Thus, sepsis, paracentesis-induced hypovolaemia, raised intra-abdominal pressure due to tense ascites, diuretic-induced hypovolaemia, lactulose-induced hypovolaemia, and any combination of these, which in the past were used to exclude HRS, are now acknowledged triggers of this condition.[14] The avoidance of hypovolaemia by albumin administration in patients with spontaneous bacterial peritonitis has been shown to decrease the incidence of AKI.[15] More importantly, multiple observational studies, several controlled trials and growing clinical experience have led to the acceptance and widespread use of terlipressin to improve GFR in this condition.[16]

RHABDOMYOLYSIS-ASSOCIATED ARF

This condition accounts for close to 5–10%[17] of cases of ARF in ICU depending on the setting. Its pathogenesis involves prerenal, renal and postrenal factors. It is now typically seen following major trauma, drug overdose with narcotics, vascular embolism, and in response to a variety of agents that can induce major muscle injury. The principles of treatment are based on retrospective data. They include prompt and aggressive fluid resuscitation, elimination of causative agents, correction of compartment syndromes, the alkalinisation of urine (pH > 6.5) and the maintenance of polyuria (>300 ml/h). The role of mannitol is controversial.

POSTRENAL RENAL FAILURE

Obstruction to urine outflow is the most common cause of functional renal impairment in the community,[18] but is uncommon in the ICU. The clinical presentation of obstruction may be acute or acute-on-chronic in patients with long-standing renal calculi. It may not always be associated with oliguria. If obstruction is suspected, ultrasonography can be easily performed at the bedside. However, not all cases of acute obstruction have an abnormal ultrasound and, in many cases, obstruction occurs in conjunction with other renal insults (e.g. staghorn calculi and severe sepsis of renal origin). Assessment of the role of each factor and overall management should be conducted in conjunction with a urologist. Finally, the sudden and unexpected development of anuria in an ICU patient should always suggest obstruction of the urinary catheter as the cause. Appropriate flushing or changing of the catheter should be implemented in this setting.

PATHOGENESIS OF ACUTE KIDNEY INJURY

The pathogenesis of obstructive AKI involves several humoral responses as well as mechanical factors. The pathogenesis of parenchymal renal failure as seen with glomerulonephritis is typically immunological. It varies from vasculitis to interstitial nephropathy and involves an extraordinary complexity of immunological mechanisms. The pathogenesis of prerenal AKI is of greater direct relevance to the intensivist.

The overwhelming majority of our conceptions of the pathophysiology of prerenal AKI are derived from animal models[19,20] using ischaemia by the acute and complete occlusion of the arterial vascular supply to the kidney.

Unfortunately, the clinical relevance of such models is limited, maybe even negligible to conditions like sepsis,[21,22] now the most common triggers of AKI in hospital and ICU patients. However, models of septic AKI that fully resemble the human phenotype are difficult to develop. When a hyperdynamic sepsis phenotype with AKI is produced in large animals, renal blood flow actually increases to supranormal levels and renal histopathology is essentially normal.[23, 24] If experimental septic AKI can occur in the setting of increased renal blood flow, it is impossible to know for sure that this does not also happen in humans. Histopathological assessment in humans remains confined to rapid postmortem assessment, and assessment of renal blood flow is similarly extremely difficult and confined to invasive techniques.

Despite all of the above observations, activation of the renin–angiotensin system (RAS), activation of

the renal sympathetic system,[25] and activation of the tubule-glomerular feedback (TGF) system seem to play a role.[26] However, it remains unclear which particular pathway of injury has *primacy* in terms of *importance or timing* or *both*. Finally, it remains unknown whether intrarenal shunting contributes to decreased GFR and ischaemia of the renal medulla. Such shunting may also be coupled with changes in the microcirculation, suggesting that, even if one could measure global renal blood flow with reasonable accuracy, unless the microcirculation is also assessed our understanding of AKI will remain poor.

THE CLINICAL PICTURE

The most common clinical picture seen in ICU is that of a patient who has sustained/is experiencing a major systemic insult (trauma, sepsis, myocardial infarction, severe haemorrhage, cardiogenic shock, major surgery and the like). When the patient arrives in the ICU, resuscitation is typically well under way or surgery may have just been completed. Despite such efforts, the patient is already anuric or oliguric, the serum creatinine is rising and a metabolic acidosis may be developing. Potassium and phosphate levels may be rising as well. Mechanical ventilation and the need for vasoactive drugs are common. Fluid resuscitation is typically undertaken in the ICU under the guidance of invasive haemodynamic monitoring. Vasoactive drugs are often used to restore MAP to 'acceptable' levels (typically >65–70 mmHg). The patient may improve over time and urine output may return with or without the assistance of diuretic agents. If urine output does not return, however, renal replacement therapy (RRT) needs to be considered. Once the cause of AKI has been removed and the patient has become physiologically stable, slow (days to weeks) recovery will typically occur. If the cause of AKI has not been adequately remedied, the patient remains gravely ill, the kidneys do not recover and death from multi-organ failure may occur.

PREVENTING ACUTE KIDNEY INJURY

The fundamental principle of AKI prevention is to treat its cause. If prerenal factors contribute, these must be identified, and haemodynamic resuscitation quickly instituted.

RESUSCITATION

Intravascular volume must be maintained or rapidly restored, and this is often best done using invasive haemodynamic monitoring (central venous catheter, arterial cannula, and pulmonary artery catheter or pulse contour cardiac output catheters in some cases). Oxygenation must be maintained. An adequate haemoglobin concentration (at least >70 g/L) must be maintained or immediately restored. Once intravascular volume has been restored, some patients remain hypotensive (mean arterial pressure (MAP) <70 mmHg). In these patients, autoregulation of renal blood flow may be lost. Restoration of MAP to near-normal levels may increase GFR. Such elevations in MAP, however, require the addition of vasopressor drugs.[27] The nephroprotective role of additional fluid therapy in a patient with a normal or increased cardiac output and blood pressure is questionable. Despite these resuscitation measures, AKI may still develop if cardiac output is inadequate. This may require a variety of interventions from the use of inotropic drugs to the application of ventricular assist devices.

NEPHROPROTECTIVE DRUGS

Following haemodynamic resuscitation and removal of nephrotoxins, it is unclear whether the use of additional pharmacological measures is of further benefit to the kidneys. A phase III trial in critically ill patients showed that low-dose dopamine is only as effective as placebo in the prevention of renal dysfunction in ICU patients.[28] The use of loop diuretics is controversial and not supported by high-quality evidence. Other agents such as theophylline, urodilatin, anaritide (a synthetic atrial natriuretic factor) and fenoldopam have failed to show consistent benefits.

In patients receiving radiocontrast saline, infusion to maintain intravascular fluid expansion is helpful in attenuating kidney injury. The relevance of such treatment in critically ill patients, however, remains unclear. The benefits of *n*-acetylcysteine and bicarbonate infusion as protective strategies in this context also remain controversial.

DIAGNOSTIC INVESTIGATIONS

An aetiological diagnosis of AKI must always be established. Such diagnosis may be obvious on clinical grounds. In other cases, investigations including the examination of urinary sediment and exclusion of a urinary tract infection (most if not all patients), the exclusion of obstruction when appropriate (some patients) and the careful exclusion of nephrotoxins (all patients) may be needed.

In specific situations, other investigations are necessary to establish the diagnosis, such as creatine kinase and free myoglobin for possible rhabdomyolysis. A chest radiograph, a blood film, the measurement of non-specific inflammatory markers, and the measurement of specific antibodies (anti-GBM, antineutrophil cytoplasm, anti-DNA, anti-smooth muscle, etc.) may help diagnose vasculitis or of certain types of collagen disease or glomerulonephritis. If thrombotic–thrombocytopenic purpura is suspected, the additional measurement of lactic dehydrogenase, haptoglobin, unconjugated bilirubin and free haemoglobin are needed. In some patients, specific findings (cryoglobulins, Bence–Jones proteins) are almost diagnostic. In a few rare patients, a renal biopsy might become necessary.

NOVEL BIOMARKERS OF AKI

Using new search techniques based on proteomics investigators have identified novel biomarkers of AKI.[29] The identification of these biomarkers may change our classification and treatment of this condition in the near future. These biomarkers appear to change significantly earlier than changes in serum creatinine.[30] They appear to reflect different aspects of renal injury. For example, cystatin C appears to reflects changes in glomerular filtration rate, while neutrophil gelatinase-associated lipocalin (NGAL) appears to reflect tubular stress/injury. They also appear to dynamically change with treatment or recovery, which suggests that they can be used to monitor interventions. They may identify sub-populations of patients who do not have AKI according to creatinine-based criteria, but actually have a degree of kidney stress/injury that can be detected by biomarkers and is associated with worse outcomes.[30] Finally, by identifying possible mechanisms of injury they may increase our understanding of the pathogenesis of AKI. Their therapeutic implications however, remain unclear.

MANAGEMENT OF ESTABLISHED ACUTE KIDNEY INJURY

The principles of management of established AKI are the treatment or removal of its cause, the avoidance of nephrotoxins and the maintenance of physiological homeostasis while recovery takes place. Complications such as encephalopathy, pericarditis, myopathy, neuropathy, electrolyte disturbances or other major electrolyte, fluid or metabolic derangement should never occur in a modern ICU. Their prevention may include several measures that vary in complexity, from fluid restriction to the initiation of extracorporeal renal replacement therapy.

Nutritional support should be started early and should contain adequate calories (20–30 kcal/kg/day) as a mixture of carbohydrates and lipids. Adequate protein (1–2 g/kg/day) should be administered. There is no evidence that specific renal nutritional solutions are useful. Vitamins and trace elements should be administered at least according to their recommended daily allowance. The role of newer immunonutritional solution remains controversial. The enteral route is preferred to the use of parenteral nutrition.

Hyperkalaemia (>6 mmol/L) must be promptly treated either with insulin and dextrose administration, the infusion of bicarbonate if acidosis is present, the administration of nebulised salbutamol, or all of the above together. If the 'true' serum potassium is >7 mmol/L or electrocardiographic signs of hyperkalaemia appear, calcium gluconate (10 mL of 10% solution i.v.) should also be administered. The above measures are temporising actions, while renal replacement therapy is being set up. The presence of hyperkalaemia is a major indication for the immediate institution of renal replacement therapy.

Metabolic acidosis is almost always present but rarely requires treatment per se. Anaemia requires correction to maintain a haemoglobin of at least >70 g/L. More aggressive transfusion needs individual patient assessment. Drug therapy must be adjusted to take into account the effect of the decreased clearances associated with loss of renal function. Stress ulcer prophylaxis is advisable. Assiduous attention should be paid to the prevention of infection.

Fluid overload can be prevented by the use of loop diuretics in polyuric patients. However, if the patient is oliguric, the only way to avoid fluid overload is to institute renal replacement therapy (RRT) at an early stage (see Ch. 48). Marked azotaemia ([urea]>40 mmol/L or [creatinine] >400 μmol/L) is undesirable and should probably be treated with RRT unless recovery is imminent or already under way and a return toward normal values is expected within 24–48 hours. It is recognised, however, that no RCTs exist to define the ideal time for intervention with artificial renal support.

PROGNOSIS

The mortality of critically ill patients with ARF remains high (40–50% depending on case-mix). It is frequently stated that patients die with renal failure rather than of renal failure. However, much indirect evidence supports a careful and proactive approach to the treatment of patients with ARF, which is based on the prevention of uncontrolled uraemia and the maintenance of low urea levels throughout the patient's illness. Finally ICU patients with AKI typically recover to baseline or near-baseline function even when suffering from severe AKI and long-term dialysis is an uncommon complication.

Renal replacement therapy

Rinaldo Bellomo

When acute kidney injury (AKI) is severe, resolution can take several days or weeks. During this time, the kidneys cannot maintain homeostasis of fluid, potassium, metabolic acid and waste products. Life-threatening complications frequently develop. In these patients, extracorporeal techniques of blood purification must be applied to prevent such complications. Such techniques, broadly named renal replacement therapy (RRT), include continuous haemofiltration and its technical variations, intermittent haemodialysis and peritoneal dialysis, each with its technical variations. All of these techniques rely on the principle of removing unwanted solutes and water through a semipermeable membrane. Such membrane is either biological (peritoneum) or artificial (haemodialysis or haemofiltration membranes) and each offers several advantages, disadvantages and limitations.

PRINCIPLES

The principles of RRT have been extensively studied and described.[1–3] This is a summary of some aspects that are relevant to the critical care physician.

WATER REMOVAL

The removal of unwanted solvent (water) is therapeutically probably as important as the removal of unwanted solute (acid, uraemic toxins, potassium and the like). During RRT, water is removed through a process called *ultrafiltration*. This process is essentially the same as that performed by the glomerulus. It requires a driving pressure to move fluid across a semipermeable membrane because such fluid would normally be kept within the circulation due to oncotic pressure (colloid osmotic pressure). This pressure is achieved by:

1. Generating a *transmembrane pressure* though pumped blood flow (as in haemofiltration or during intermittent haemodialysis) that is greater than oncotic pressure
2. Increasing osmolarity of the dialysate (as in peritoneal dialysis).

SOLUTE REMOVAL

The removal of unwanted solute can be achieved by:

1. Creating an electrochemical gradient across the membrane using a flow-past system with toxin-free dialysate (*diffusion*) as in intermittent haemodialysis (IHD) and peritoneal dialysis (PD)
2. Creating a transmembrane-pressure-driven 'solvent drag', where solutes move together with solvent (*convection*) across a porous membrane, are discarded together with the solvent and then replaced with toxin-free replacement fluid as in haemofiltration (HF).

The rate of diffusion of a given solute depends on its molecular weight, the porosity of the membrane, the blood flow rate, the dialysate flow rate, the degree of protein binding, and its concentration gradient across the membrane. If standard, low-flux, cellulose-based membranes are used, middle molecules of >500 Daltons (D) molecular weight (MW) cannot be removed. If synthetic high-flux membranes are used (cut-off at 10–20 kiloDaltons (kD) in MW), larger molecules can be removed. With these membranes, convection is superior to diffusion in achieving the clearance of middle molecules.

INDICATIONS FOR RENAL REPLACEMENT THERAPY

In the critically ill patient, RRT should be initiated early, prior to the development of complications. Fear of early RRT stems from historical experience with the adverse effects of conventional intermittent haemodialysis (IHD) with cuprophane membranes, especially haemodynamic instability, and from the risks and limitations of continuous or intermittent PD.[4–5] However, continuous renal replacement therapy (CRRT)[6,7] or slow extended daily dialysis (SLEDD)[8] minimise these effects. The criteria for the initiation of RRT in patients with chronic renal failure are probably inappropriate in the critically ill.[9,10] A set of modern criteria for the initiation of RRT in the ICU is presented in **Box 48.1**.

With IHD or CRRT or SLEDD, there are limited data on what is 'adequate' intensity of dialysis. However, the concept of dialytic adequacy should include maintenance of homeostasis at all levels[10] and better uraemic control may translate into better survival.[11,12] An appropriate target urea might be 15–25 mmol/L, with a

Box 48.1 Modern criteria for the initiation of RRT in the ICU*

1. Oliguria (urine output <200 mL/12 hours)
2. Anuria (urine output: 0–50 mL/12 hours)
3. [Urea]>35 mmol/L
4. [Creatinine]>400 µmol/L
5. $[K^+]$>6.5 mmol/L or rapidly rising†
6. Pulmonary oedema unresponsive to diuretics
7. Uncompensated metabolic acidosis (pH<7.1)
8. $[Na^+]$<110 and >160 mmol/L
9. Temperature >40°C
10. Uraemic complications (encephalopathy/myopathy/neuropathy/pericarditis)
11. Overdose with a dialysable toxin (e.g. lithium)

**If one criterion is present, RRT should be considered. If two criteria are simultaneously present, RRT is strongly recommended.*

†Please be aware of differences between plasma vs serum measurement in your laboratory.

protein intake around 1.5 g/kg/day. This can be easily achieved using CRRT at urea clearances of 20–25 mL/kg/h depending on catabolic rate. If intermittent therapy is used, daily and extended treatment as described with SLEDD may be desirable in the ICU.[13]

MODALITY OF RENAL REPLACEMENT THERAPY

There is a great deal of controversy as to which modality of RRT is 'best' in the ICU, due to the lack of randomised controlled trials comparing different modalities (IHD or CRRT). In their absence, modalities of RRT may be judged on the basis of the following criteria:

1. Haemodynamic side-effects
2. Ability to control fluid status
3. Biocompatibility
4. Risk of infection
5. Uraemic control
6. Avoidance of cerebral oedema
7. Ability to allow full nutritional support
8. Ability to control acidosis
9. Absence of specific side-effects
10. Cost.

In relation to the above criteria, CRRT and slow low-efficiency daily dialysis (SLEDD) offer many advantages over PD and conventional IHD (3–4 hours/day, 3–4 times/week)[13] and, while CRRT or SLEDD are almost exclusively used in Australia and New Zealand,[14] only a percentage of American ICU patients receive CRRT. Irrespective of the choice of modality, some salient aspects of CRRT, IHD and PD require discussion.

CONTINUOUS RENAL REPLACEMENT THERAPY

First described in 1977, CRRT has undergone several technical modifications. It is now performed using double-lumen catheters and peristaltic blood pumps

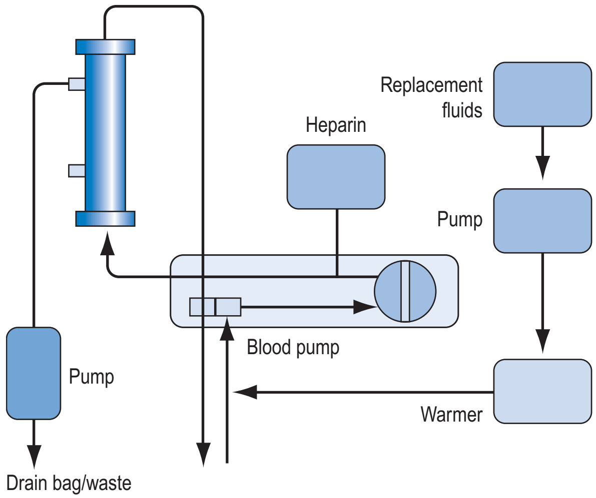

Figure 48.1 A continuous veno-venous haemofiltration (CVVH) circuit.

with control of ultrafiltration rate. If no dialysate is used and effluent is replaced with replacement solutions, the technique is called continuous veno-venous haemofiltration (CVVH). During CVVH, ultrafiltration rates of 2 L/h yield urea clearances of approximately 25 mL/kg/h in the average 80-kg patient. Diagrams illustrating typical haemofiltration circuits are presented in **Figures 48.1–48.3**.

In a veno-venous system, dialysate can also be delivered countercurrent to blood flow (continuous veno-venous haemodialysis/haemodiafiltration) to achieve either almost pure diffusive clearance or a mixture of diffusive and convective clearance.

No matter what technique is used, the following outcomes are predictable:

1. Continuous control of fluid status
2. Haemodynamic stability
3. Control of acid–base status
4. Ability to provide protein-rich nutrition while achieving uraemic control
5. Control of electrolyte balance, including phosphate and calcium balance
6. Prevention of swings in intracerebral water
7. Minimal risk of infection
8. High level of biocompatibility.

However, CRRT mandates the presence of specifically trained nursing and medical staff 24 hours a day and the issues of continuous circuit anticoagulation or the potential risk of bleeding have been of concern.

CIRCUIT ANTICOAGULATION

The flow of blood through an extracorporeal circuit causes activation of the coagulation cascade and promotes clotting of the filter and circuit itself. In order to delay such clotting and achieve acceptable operational lives (approximately 24 hours) for the circuit,

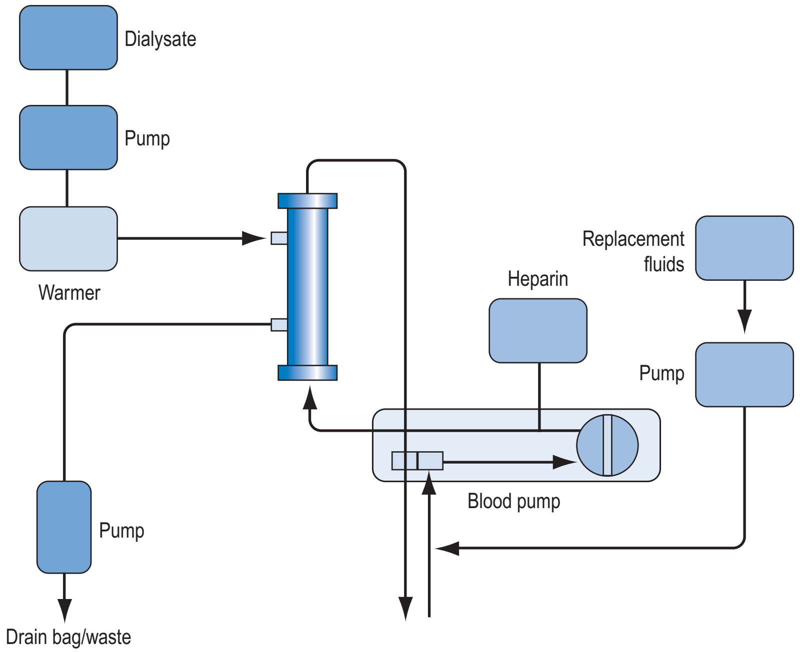

Figure 48.2 A continuous veno-venous haemodiafiltration (CVVHDF) circuit.

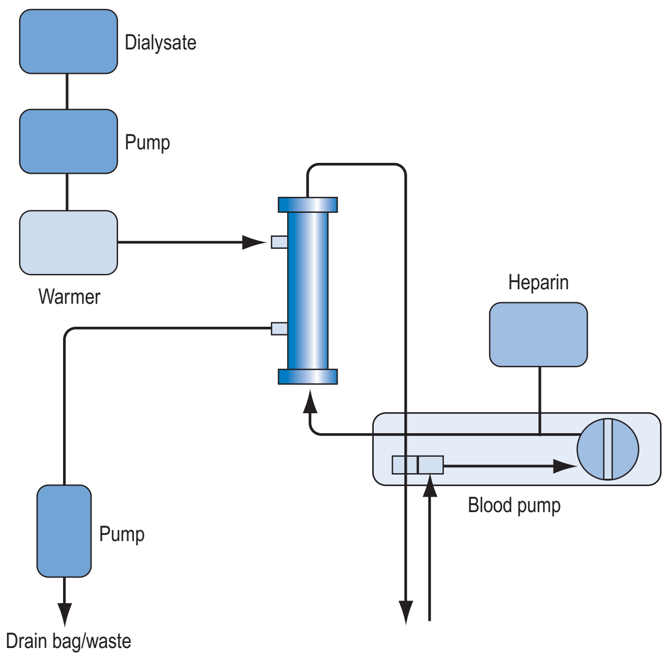

Figure 48.3 A continuous veno-venous hemodialysis (CVVHD) circuit.

anticoagulants are frequently used.[15] However, circuit anticoagulation increases the risk of bleeding. Therefore, the risks and benefits of more or less intense anticoagulation and alternative strategies (**Box 48.2**) must be considered.

In the vast majority of patients, low-dose heparin (<500 IU/h) is sufficient to achieve adequate (approximately 24 hours) circuit life, is easy and cheap to administer and has almost no effect on the patient's coagulation tests. In some patients, a higher dose is necessary. In others (pulmonary embolism, myocardial ischaemia) full heparinisation may actually be concomitantly indicated.

Regional citrate anticoagulation is very effective but requires a special dialysate or replacement fluid.[16] Nevertheless, it is safe and effective in patients who do not have liver failure. In patients with liver failure, citrate may accumulate and induce a coagulopathy. The

Box 48.2 Strategies for circuit anticoagulation during CRRT

1. No anticoagulation
2. Low-dose pre-filter heparin (<500 IU/h)
3. Medium-dose pre-filter heparin (500–1000 IU/h)
4. Full heparinisation
5. Regional anticoagulation (pre-filter heparin and post-filter protamine usually at a 100 IU : IU 1 mg ratio) (1500 IU/h of heparin pre-filter and 15 mg/h of protamine post-filter)
6. Regional citrate anticoagulation (pre-filter citrate and post-filter calcium and magnesium – special calcium-free dialysate needed or citrate-containing replacement fluid delivered pre-filter)
7. Low-molecular-weight heparin
8. Prostacyclin
9. Heparinoids

biochemical signs of citrate accumulation are an increasing base deficit, an increasing requirement for calcium administration to maintain the target level of calcaemia and widening of the total calcium to ionised calcium ratio. Magnesium supplementation is also needed. Due to development of commercially available dialysate and replacement fluids to facilitate citrate anticoagulation, and due to new CRRT machine technology to enable such anticoagulation to be performed with minimal risk, the use of citrate anticoagulation is rapidly expanding.[17]

Regional heparin/protamine anticoagulation is also somewhat complex, but simpler than citrate anticoagulation, and may be useful if frequent filter clotting occurs and further anticoagulation of the patient is considered dangerous. Low-molecular-weight heparin is also easy to administer, but more expensive. If enoxaparin is used, its dose should be adjusted for the loss of renal function. Heparinoids and prostacyclin may be useful if the patient has developed heparin-induced thrombocytopenia and thrombosis. Finally, in perhaps 10–20% of patients anticoagulation of any kind is best avoided because of endogenous coagulopathy or recent surgery or inability to metabolise citrate. In such patients, adequate filter life can be achieved provided that blood flow is kept at about 200 mL/min and vascular access is reliable.[18]

Many circuits clot for *mechanical reasons* (e.g. inadequate access, unreliable blood flow from double-lumen catheter depending on patient position, kinking of catheter). Responding to frequent filter clotting by simply increasing anticoagulation without making the correct aetiological diagnosis (e.g. checking catheter flow and position, taking a history surrounding the episode of clotting, identifying the site of clotting) is often futile and exposes the patient to unnecessary risk. Particular attention needs to be paid to the adequacy/ease of flow through the double-lumen catheter. Smaller (11.5 Fr) catheters in the subclavian position are a particular problem. Larger catheters (13.5 Fr) in the femoral position or internal jugular position appear to perform more reliably.[19]

CRRT TECHNOLOGY

The increasing use of veno-venous CRRT has led to the development of a field of CRRT technology, which offers different kinds of machines to facilitate its performance.[20] Some understanding of these devices is important to the successful implementation of CRRT in any ICU. These machines are safer and have much more sophisticated pump control systems, alarms and graphic displays. They are much more user-friendly, especially with respect to the set-up procedure. They provide information on outflow pressure (the suction pressure applied to the outflow lumen of the dialysis catheter and a marker of its performance), the transmembrane pressure (a marker of membrane fouling and clotting) and inflow pressure (a marker of resistance to inflow). Such pressures are often useful is assessing catheter function and the aetiology of circuit loss.

The choice of membrane is also a matter of controversy. There are no controlled studies to show that one of them confers a clinical advantage over the others. The AN 69 is the most commonly used CRRT membrane in Australia. The issue of membrane size is also controversial as no controlled studies have compared different membrane surface sizes. If high-volume haemofiltration is planned, however, the membrane surface needs to be in the 1.6–2 m^2 range.

INTENSITY OF CRRT

The optimal dose (expressed at effective effluent/kg/h) of CRRT has been the subject of controversy for almost a decade. Several studies had initially suggested that higher dose may translate into better outcome.[21–23] However, such studies had been single centre in nature and were considered to require confirmation in multicentre randomised controlled trials. Two such trials were completed in 2008[24] and 2009.[25] Both showed no difference with increasing the intensity of RRT indicating that, in current practice, the prescribed dose of RRT should be equivalent to 25–30 mL/kg/h to take into account the impact of 'down-time' on delivered dose. Moreover, essentially all AKI patients on vasopressor support received CRRT in the ATN and RENAL trial. Thus, by practice consensus, CRRT has now become the de facto standard of care in haemodynamically unstable patients. Renal recovery was much greater in the RENAL trial (with essentially exclusive use of CRRT) than in the ATN trial (with substantial use of IHD) suggesting that the use of CRRT might facilitate renal recovery.

INTERMITTENT HAEMODIALYSIS

Vascular access is typically by double-lumen catheter as in continuous haemofiltration. The circuit is also the

same. Countercurrent dialysate flow is used as in CVVHD. The major differences are that standard IHD uses high dialysate flows (300–400 mL/min), generates dialysate by mixing purified water and concentrate and treatment is applied for short periods of time (3–4 hours), usually every second day. These differences have important implications. Firstly, volume has to be removed over a short period of time and this may cause hypotension. Repeated hypotensive episodes may delay renal recovery.[4] Secondly, solute removal is episodic. This translates into inferior uraemic control[26] and acid–base control. Limited fluid and uraemic control imposes unnecessary limitations on nutritional support. Furthermore, rapid solute shifts increase brain water content and raise intracranial pressure.[27] Finally, much controversy has surrounded the issue of membrane bioincompatibility. Standard low-flux dialysing membranes made of cuprophane are known to trigger the activation of several inflammatory pathways, compared with high-flux synthetic membranes (also used for continuous haemofiltration). It is possible that such pro-inflammatory effect contributes to further renal damage and delays recovery or even affects mortality. Given the minimal difference in cost between biocompatible and bioincompatible low-flux membranes, biocompatible (polysulfone) membranes are now preferred.

The limitations of applying 'standard' IHD to the treatment of ARF[9] have led to the development of new approaches (so-called 'hybrid techniques') such as SLEDD.[13] These techniques seek to adapt IHD to the clinical circumstances and thereby increase its tolerance and its clearances.

PERITONEAL DIALYSIS

This technique is now uncommonly used in the treatment of adult ARF in developed countries.[23] However, it may be an adequate technique in developing countries or in children where the peritoneal membrane has a greater relative surface or alternatives are considered too expensive, too invasive, or are not available. Typically access is by the insertion of an intraperitoneal catheter. Glucose-rich dialysate is then inserted into the peritoneal cavity and acts as the 'dialysate'. After a given 'dwell time' it is removed and discarded with the extra fluid and toxins that have moved from the blood vessels of the peritoneum to the dialysate fluid. Machines are also available that deliver and remove dialysate at higher flows providing intermittent treatment or higher solute clearances. Several major shortcomings make PD relatively unsuited to the treatment of adult ARF:

1. Limited and sometimes inadequate solute clearance
2. High risk of peritonitis
3. Unpredictable hyperglycemia
4. Fluid leaks
5. Protein loss
6. Interference with diaphragm function.

There have not been any reports of the sole use of PD for the treatment of adult patients with ARF in the last 15 years. A randomised trial comparing PD with CVVH found that PD was associated with increased mortality.[28]

OTHER BLOOD PURIFICATION TECHNIQUES

HAEMOPERFUSION

During haemoperfusion, blood is circulated through a circuit similar to one used for CVVH. However, a charcoal cartridge is perfused with blood instead of a dialysis membrane. In some cases an ion exchange resin (Amberlite) has been used. Charcoal microcapsules effectively remove molecules of 300–500 D in molecular weight; including some lipid-soluble and protein-bound substances. Heparinisation is necessary to prevent clotting. Attention must also be paid to changes in intravascular volume at the start of therapy because of the large priming volume of the cartridge (260 mL). Glucose absorption is significant and monitoring of blood glucose is necessary to avoid hypoglycaemia. Also thrombocytopenia is common, and can be marked. The role of haemoperfusion is controversial, as no controlled trials have ever shown it to confer clinically significant advantages. It may be useful, however, in patients with life-threatening theophylline overdose because it removes the agent effectively.

PLASMAPHERESIS OR PLASMA EXCHANGE

With this technique, plasma is removed from the patient and exchanged with fresh frozen plasma (FFP) and a mixture of colloid and crystalloid solutions. This technique can also be performed in an ICU familiar with CRRT techniques. A plasmafilter (a filter that allows the passage of molecules up to 500 kD) instead of a haemofilter is inserted in the CVVH circuit, and the filtrate (plasma) discarded. Plasmapheresis can also be performed with special machines using the principles of centrifugation. The differences, if any, between centrifugation and filtration technology are unclear. Replacement (post-filter) will occur as in CVVH using, for example, a 50/50 combination of FFP and albumin. Plasmapheresis has been shown to be effective treatment for thrombotic thrombocytopenic purpura (TTP) and for several diseases mediated by abnormal antibodies (Guillain–Barré syndrome, cryoglobulinaemia, myasthenia gravis, Goodpasture syndrome, etc.) in which antibody removal appears desirable. Its role in the treatment of sepsis remains uncertain.[29]

BLOOD PURIFICATION TECHNOLOGY OUTSIDE OF ARF

There is growing interest in the possibility that blood purification may provide a clinically significant benefit in patients with severe sepsis/septic shock by

removing circulating 'mediators'. A variety of techniques including plasmapheresis, high-volume haemofiltration, very-high-volume haemofiltration, and coupled plasma filtration adsorption and large-pore haemofiltration[29-31] are being studied in animals and in phase I/II studies in humans. Initial experiments support the need to continue exploring this therapeutic option. However, no suitably powered randomised controlled trials have yet been reported. Also, blood purification technology in combination with bioreactors containing either human or porcine liver cells is under active investigation as a form of artificial liver support for patients with fulminant liver failure or for patients with acute-on-chronic liver failure. Albumin-based dialysis has been developed to deal with protein-bound toxins in patients with liver failure. This system, known as MARS (molecular adsorption recirculating system), has shown benefits in patients with elevated intracranial pressure and/or acute-on-chronic liver failure, but not in patients with fulminant liver failure.[32]

DRUG PRESCRIPTION DURING DIALYTIC THERAPY

Acute renal failure and RRT profoundly affect drug clearance. A comprehensive description of changes in drug dosage according to the technique of RRT, residual creatinine clearance and other determinants of pharmacodynamics is beyond the scope of this chapter and can be found in specialist texts.[33] **Table 48.1** provides general guidelines for the prescription of drugs commonly used in the ICU.

Table 48.1 Drug dosage during dialytic therapy*

DRUG	CRRT	IHD
Aminoglycosides	Normal dose q. 36 h	50% normal dose q. 48 h–2/3 re-dose after IHD
Cefotaxime or Ceftazidime	1g q. 8–12 h	1g q. 12–24 h after IHD
Imipenem	500 mg q. 8 h	250 mg q. 8 h and after IHD
Meropenem	500 mg q. 8 h	250 mg q. 8 h and after IHD
Metronidazole	500 mg q. 8 h	250 mg q. 8 h and after IHD
Co-trimoxazole	Normal dose q 18 h	Normal dose q 24 h after IHD
Amoxicillin	500 mg q. 8 h	500 mg daily and after IHD
Vancomycin	1 g q. 24 h	1 g q. 96–120 h
Piperacillin	3–4 g q. 6 h	3–4 g q. 8 h and after IHD
Ticarcillin	1–2 g q. 8 h	1–2 g q. 12 h and after IHD
Ciprofloxacin	200 mg q. 12 h	200 mg q. 24 h and after IHD
Fluconazole	200 mg q. 24 h	200 mg q. 48 h and after IHD
Aciclovir (acyclovir)	3.5 mg/kg q. 24 h	2.5 mg/kg/d and after IHD
Ganciclovir	5mg/kg/d	5mg/kg/48 h and after IHD
Amphotericin B	Normal dose	Normal dose
Liposomal amphotericin	Normal dose	Normal dose
Ceftriaxone	Normal dose	Normal dose
Erythomycin	Normal dose	Normal dose
Milrinone	Titrate to effect	Titrate to effect
Amrinone	Titrate to effect	Titrate to effect
Catecholamines	Titrate to effect	Titrate to effect
Ampicillin	500 mg q 8 hourly	500 mg daily and after IHD

*The above values represent approximations and should be used as a general guide only. Critically ill patients have markedly abnormal volumes of distribution for these agents, which will affect dosage. CRRT is conducted at variable levels of intensity in different units, also requiring adjustment. The values reported here relate to CVVH at 2 L/h of ultrafiltration. Vancomycin is poorly removed by CVVHD. IHD may also differ from unit to unit. The values reported here relate to standard IHD with low-flux membranes for 3–4 hours every second day. D=day; q=frequency; h=hours.

SUMMARY

The field of renal replacement therapy has undergone remarkable changes over the last 10 years and is continuing to evolve rapidly. Technology is being improved to facilitate clinical application and new areas of research are developing. CRRT is now firmly established throughout the world as perhaps the most commonly used form of RRT. Conventional dialysis, however, which was slowly losing ground, is reappearing in the form of extended, slow-efficiency treatment, especially in the USA. Two large-phase III trials (>1000 patients) have been completed in the USA and in Australia/New Zealand to define the optimal dose of RRT in ICU patients and the results indicate that a dose of 25/kg/h of effluent generation provides appropriate therapy in this setting. In the meanwhile the use of novel membranes, sorbents and different intensities of treatment are being explored in the area of sepsis management and liver support. Intensivists need to keep abreast of this rapid evolution if they are to offer their patients the best of care.

Disorders of consciousness

Balasubramanian Venkatesh

NEUROANATOMY AND PHYSIOLOGY OF WAKEFULNESS

A normal level of consciousness depends on the interaction between the cerebral hemispheres and the rostral reticular activating system (RAS) located in the upper brainstem. Although the RAS is a diffuse projection, the areas of RAS of particular importance to the maintenance of consciousness are those located between the rostral pons and the diencephalon. In contrast, however, consciousness is not focally represented in any of the cerebral hemispheres and is in many ways related to the mass of functioning cortex. Thus anatomical bilateral hemispheric lesions or brainstem lesions may result in an altered conscious state.[1] Large unilateral hemispheric lesions may produce impairment of consciousness by compression of the upper brainstem. In addition metabolic processes may also result in coma from interruption of energy substrate delivery or alteration of neuronal excitability. Disorders of consciousness are characterised either by an alteration in the level or by content of consciousness (**Box 49.1**). These are also illustrated in **Figure 49.1**.

The last three conditions described in Box 49.1 are a frequent source of confusion and require further discussion (**Table 49.1**). These neurological states are seen more frequently in modern day clinical practice partly because of the advances in therapy of severe brain injury and intensive care, which have led to the survival of many patients who would have otherwise died.

DIFFERENTIAL DIAGNOSIS OF COMA

Although the aetiology of coma is invariably multifactorial, the differential diagnosis of coma can be broadly grouped into three classes:

- diseases that produce focal or lateralising signs
- coma without focal or lateralising signs, but with signs of meningeal irritation
- coma without focal or lateralising signs or signs of meningeal irritation.

These are considered in greater detail in **Table 49.2**.

CLINICAL EXAMINATION OF THE COMATOSE PATIENT

The neurological examination of the comatose patient is of crucial importance to assess the depth of coma and to locate the site of lesion. Although the detailed neurological examination that can be carried out in a conscious patient is not possible in a comatose individual, useful information can be obtained by performing a thorough general examination and a neurological examination, particularly evaluating the level of consciousness, brainstem signs and motor responses in coma.

GENERAL EXAMINATION

General examination of the patient may point to the aetiology of coma. Skin changes may be seen in carbon monoxide poisoning (cherry-red discolouration of skin), alcoholic liver disease (telangiectasia, clubbing), hypothyroidism (puffy facies) and hypopituitarism (sallow complexion). The presence of cutaneous petechiae or ecchymoses may point to meningococcaemia, rickettsial infection or endocarditis as possible causes of coma. Needle puncture marks may suggest substance abuse. Bullous skin lesions are a feature of barbiturate overdose. An excessively dry skin may indicate diabetic ketoacidosis or anticholinergic overdose.

Periorbital haematomas (raccoon eyes) indicate an anterior basal skull fracture, particularly if there is associated cerebrospinal fluid rhinorrhoea. The other signs of a basal skull fracture include Battle's sign and cerebrospinal fluid otorrhoea. Nuchal rigidity may be seen in meningoencephalitis and subarachnoid haemorrhage, although this sign may not be present in the elderly and in patients in deep coma.

The presence of hepatomegaly or stigmata of chronic liver disease may suggest hepatic encephalopathy. Bilateral enlarged kidneys may indicate polycystic kidney disease and should prompt one to consider subarachnoid haemorrhage as a possible aetiology of coma. The breath may smell of alcohol or other poisons (organophosphates). The smell of ketones in the breath is an unreliable sign and hepatic and uraemic foetor are rare.

Box 49.1 Disorders of consciousness

Consciousness	An awake individual demonstrates full awareness of self and environment
Confusion	Inability to think with customary speed and clarity, associated with inattentiveness, reduced awareness and disorientation
Delirium	Confusion with agitation and hallucination
Stupor	Unresponsiveness with arousal only by deep and repeated stimuli
Coma	Unarousable unresponsiveness
Locked-in syndrome	Total paralysis below third cranial nerve nuclei; normal or impaired mental function
Persistent vegetative state	Prolonged coma >1 month, some preservation of brainstem and motor reflexes
Akinetic mutism	Prolonged coma with apparent alertness and flaccid motor tone
Minimally conscious state	Preserved wakefulness, awareness and brainstem reflexes, but poorly responsive

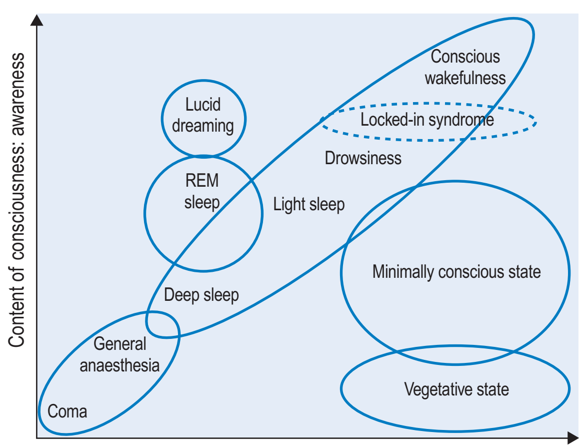

Figure 49.1 Disorders of consciousness are characterised by an alteration in either the level or content of consciousness. *(From Gosseries et al. Disorders of Consciousness: Coma, Vegetative and Minimally Conscious States. In: Cvetkovic D, Cosic I, editors. States of Consciousness: Experimental Insights into Meditation, Waking, Sleep and Dreams. Berlin: Springer; 2011, with permission.)*

LEVEL OF CONSCIOUSNESS

This is assessed by the Glasgow Coma Scale (GCS),[2] which takes into account the patient's response to command and physical stimuli. The GCS (**Table 49.3**), which was originally developed to grade the severity of head injury and prognosticate outcome, has now been extended for all causes of impaired consciousness and coma. Although it is a simple clinical score easily performed by both medical and nursing staff by the bedside, there are a number of caveats:

1. The GCS should always be determined prior to administration of sedative drugs or endotracheal intubation.
2. It should also be defined with regard to patient's vital signs, namely blood pressure, heart rate and temperature.
3. The GCS must be interpreted in light of previous or concomitant drug therapy.
4. The presence of alcohol in the breath or in the serum should always be documented.
5. Because of the considerable inter-observer variation in scoring, it is important to define the responses in descriptive terms rather than emphasising the numerical score associated with each response.
6. The measurement of awareness by the GCS is limited. Subtle changes in brainstem reflexes are not adequately assessed by the GCS.

To overcome the limitations of the GCS in assessing brain stem activity, the FOUR (Full Outline of UnResponsiveness) score was proposed by Wijdicks et al.[3,4] The components of the FOUR score include eye movements, motor score, brainstem reflexes and respiration. Each subcomponent is scored out of a maximum of four and therefore the maximum score is 16. It does not include verbal response and may be more suitable in the intubated patient.

PUPILLARY RESPONSES IN COMA[5]

The presence of normal pupils (2–5 mm and equal in size and demonstrate both direct and consensual light reflexes) confirms the integrity of the pupillary pathway (retina, optic nerve, optic chiasma and tracts, midbrain and third cranial nerve nuclei and nerves). The size of the pupil is a balance between the opposing influences of both sympathetic (causing dilatation) and parasympathetic (causing constriction) systems. Pupillary abnormalities have localising and diagnostic value in clinical neurology (**Table 49.4**). When the pupils are miosed, the light reaction is difficult to appreciate and may require a magnifying glass.

OPHTHALMOSCOPY IN COMA

The pupils *should never be dilated pharmacologically* without prior documentation of the pupillary size and the light reflex. The presence of papilloedema suggests

Table 49.1 Coma-like syndromes and related states

SYNDROME	FEATURES	SITE OF LESION	EEG	METABOLISM (% OF NORMAL)[49]	COMMENTS
Locked-in syndrome[50] (de-efferented state)	Alert and aware, vertical eye movements present, and able to blink Quadriplegic, lower cranial nerve palsies, no speech, facial or pharyngeal movements	Bilateral anterior pontine lesion which transects all descending motor pathways, but spares ascending sensory and RAS systems	Normal	90–100%	Similar state seen with severe polyneuropathies, myasthenia gravis and neuromuscular blocking agents
Persistent vegetative state (PVS)[51] (apallic syndrome, neocortical death)	Previously comatose, who now appear to be awake. Spontaneous limb movements, eye movements and yawning seen. However, patient inattentive, no speech, no awareness of environment and total inability to respond to commands	Extensive damage to both cerebral hemispheres with relative preservation of the brainstem	Polymorphic delta or theta waves, sometimes alpha	40–60%	When vegetative state lasts longer than 4 weeks, it is termed persistent. PVS lasting for longer than 2 weeks implies a poor prognosis
Akinetic mutism[52] (coma vigile)	Partially or fully awake patient, immobile and silent	Lesion in bilateral frontal lobes or hydrocephalus or third ventricular masses	Diffuse slowing	40–80%	Abulia is the term applied to milder forms of akinetic mutism
Catatonia	Awake patients, sometimes a fixed posture, muteness with decreased motor activity	Usually of psychiatric origin	Non-specific EEG patterns associated with medical conditions	Variable metabolic changes in prefrontal cortex	May be mimicked by frontal lobe disease and drugs
Minimally conscious state[49]	Globally impaired responsiveness, limited but discernible evidence of self and environment	Global neuronal damage	Theta and alpha waves	40–60%	Differs from PVS in that patients diagnosed with minimally conscious state have some level of awareness

the presence of intracranial hypertension, but is frequently absent when the lesion is acute. Subhyaloid and vitreous haemorrhages are seen in patients with subarachnoid haemorrhage.[6]

EYE MOVEMENTS IN COMA[7]

Horizontal eye movements to the contralateral side are initiated in the ipsilateral frontal lobe and closely coordinated with the corresponding centre in the contralateral pons. To facilitate conjugate eye movements, yoking of the 3rd, 4th and 6th nerve nuclei is achieved by the medial longitudinal fasciculus.

To look to the left, the movement originates in the right frontal lobe and is coordinated by the left pontine region and vice versa. In contrast to horizontal gaze, vertical eye movements are under bilateral control of the cortex and upper midbrain.

The position and movements of the eyes are observed at rest. The presence of spontaneous roving eye movements excludes brainstem pathology as a cause of coma. In a paralytic frontal lobe pathology the eyes will deviate towards the side of the lesion, whereas in pontine pathologies the eyes will deviate away from the side of the lesion. Ocular bobbing, an intermittent downward jerking eye movement, is seen in pontine lesions owing to loss of horizontal gaze and unopposed midbrain-controlled vertical gaze activity[8]. Skew deviation (vertical separation of the ocular axes) occurs with pontine and cerebellar disorders[9].

Table 49.2 Differential diagnosis of coma

CATEGORY	SPECIFIC DISORDER	FEATURES IN HISTORY AND EXAMINATION	INVESTIGATIONS	COMMENTS
Coma with focal signs	*Trauma* – extradural, subdural and parenchymal haemorrhage, concussions	History of trauma, findings of fracture base of skull, scalp haematoma, other associated body injuries	Usually an abnormal CT	Exclude coexisting drug or alcohol ingestion
	Vascular –intracerebral haemorrhage	Sudden onset, history of headaches or hypertension, neck stiffness may be present	Abnormal CT scan	Consider causes of secondary hypertension in young hypertensives
	Vascular – thromboembolic	Sudden onset, atrial fibrillation, vascular bruits, endocarditis	An abnormal CT after a few days	Consider echocardiography to diagnose cardiac sources of emboli
	Brain abscess	Subacute onset, look for ENT and dental sources of infection	Abnormal CT and CSF	Consider infective endocarditis and suppurative lung disease as sources of sepsis
Coma without focal signs, but with meningeal irritation	Infection Meningitis, encephalitis	Onset of illness over a few hours to days, neck stiffness, rash of meningococcaemia	Abnormal CSF	Consider underlying immunosuppressive states
	Subarachnoid haemorrhage	Onset usually sudden, subhyaloid haemorrhages on fundoscopy	Abnormal CT and CSF	Consider polycystic kidney disease in subarachnoid haemorrhage
Coma without focal signs and no meningeal irritation	Metabolic causes Hyponatraemia Hypoglycaemia, hyperglycaemia Hypoxia Hypercapnia Hypo- and hyperthermia Hyper- and hypo-osmolar states	History might point to the cause of metabolic disturbance, asterixis a feature of hypercapnia-induced coma	Abnormal blood results	Rapid correction of hyponatraemia and osmolality should be avoided
	Endocrine causes Myxoedema Adrenal insufficiency Hypopituitarism	Puffy facies, may be hypothermic	Abnormal electrolyte profile, hypoglycaemia	Multiple disorders may be present in the same patient
	Seizure disorders	History typical	Abnormal EEG, check anticonvulsant levels	CT scan to exclude an underlying space-occupying lesion
	Organ failure Hepatic Renal	History of jaundice, chronic alcohol ingestion, stigmata of liver disease, asterixis	Abnormal hepatic and renal functions	Presence of A–V fistula may be a pointer to chronic renal failure
	Toxic/drug Sedatives Narcotics Alcohol Psychotropic Carbon monoxide Poisons	History, may be hypothermic at presentation except in psychotropic drug overdose	Metabolic screen is usually normal	Rapid improvement in conscious states with antidotes
	Behavioural Sleep deprivation Pseudocoma	No typical features	No specific diagnostic tests	Diagnosis of exclusion

Table 49.3 Glasgow Coma Scale

EYE OPENING	POINTS
Spontaneous	4
To speech	3
To pain	2
Nil	1
BEST VERBAL RESPONSE	
Oriented	5
Confused	4
Inappropriate	3
Incomprehensible	2
Nil	1
Intubated	T
BEST MOTOR RESPONSE	
Obeys commands	6
Localises to pain	5
Withdraws to pain	4
Abnormal flexion	3
Extensor response	2
Nil	1

The presence of full and conjugate eye movements in response to oculocephalic and oculovestibular stimuli demonstrates the functional integrity of a large segment of the brainstem. Corneal reflexes are preserved until late in coma. Upward rolling of the eyes after corneal stimulation (Bell's phenomenon) implies intact midbrain and pontine function.

LIMB MOVEMENTS AND POSTURAL CHANGES IN COMA

Restlessness, crossing of legs and spontaneous coughing, yawning, swallowing and localising movements suggest only a mild depression of the conscious state. Choreoathetotic or ballistic movements suggest a basal ganglion lesion. Myoclonic movements indicate a metabolic disorder usually of post-anoxic origin. Asterixis is seen with metabolic encephalopathies. Hiccup is a non-specific sign and does not have any localising value.

Decerebrate rigidity is characterised by stiff extension of the limbs, internal rotation of the arms and plantar flexion of the ankles. With severe rigidity, opisthotonos and jaw clenching may be observed. These movements may be unilateral or bilateral, and spontaneous or in response to a noxious stimulus. Whereas animal studies suggest that the lesion is usually in the midbrain or caudal diencephalon (leading to exaggeration of antigravity reflexes), in humans such posturing may be seen in a variety of disease states: midbrain lesion, certain metabolic disorders such as

Table 49.4 Pupillary abnormalities in coma

ABNORMALITY	CAUSE	NEUROANATOMICAL BASIS
MIOSIS (<2 MM IN SIZE)		
Unilateral	Horner's syndrome Local pathology	Sympathetic paralysis Trauma to sympathetics
Bilateral	Pontine lesions Thalamic haemorrhage Metabolic encephalopathy Drug ingestion Organophosphate Barbiturate Narcotics	Sympathetic paralysis Cholinesterase inhibition Central effect
MYDRIASIS (>5 MM IN SIZE)		
Unilateral fixed pupil	Midbrain lesion Uncal herniation	3rd nerve damage Stretch of 3rd nerve against the petroclinoid ligament
Bilateral fixed pupils	Massive midbrain haemorrhage Hypoxic cerebral injury *DRUGS* Atropine Tricyclics Sympathomimetics	Bilateral 3rd nerve damage Mesencephalic damage Paralysis of parasympathetics Prevent local reuptake of catecholamines by nerve endings Stimulation of sympathetics

Table 49.5 Disorders of respiratory rate and pattern in coma

ABNORMALITY	SIGNIFICANCE
Bradypnoea	Drug-induced coma, hypothyroid coma
Tachypnoea	Central neurogenic hyperventilation (mid brain lesion), metabolic encephalopathy
Cheyne–Stokes respiration	Deep cerebral lesions, metabolic encephalopathy (hyperpnoea alternating regularly with apnoea)
Apneustic breathing (an inspiratory pause)	Pontine lesions
Ataxic breathing (ataxic breathing normally progresses to agonal gasps and terminal apnoea)	Medullary lesions

hypoglycaemia, anoxia, hepatic coma and in drug intoxication. Decorticate posturing is characterised by flexion of elbows and wrists and extension of the lower limbs. The lesion is usually above the midbrain in the cerebral white matter.

RESPIRATORY SYSTEM[10]

Abnormal respiratory rate and patterns have been described in coma, but their precise localising value is uncertain. As a general rule, at lighter levels of impaired consciousness tachypnoea predominates, whereas respiratory depression increases with the depth of coma. Some of the commonly observed respiratory abnormalities are summarised in **Table 49.5**. Respiratory failure in comatose patients may result from hypoventilation, aspiration pneumonia and neurogenic pulmonary oedema, a sympathetic nervous system mediated syndrome seen in acute brain injury.

BODY TEMPERATURE IN COMA

The presence of altered core body temperature is a useful aid in the diagnosis of coma. Hypothermia (<35°C) is frequently observed with alcohol or barbiturate intoxication, sepsis with shock, drowning, hypoglycaemia, myxoedema coma and exposure to cold. Severe hyperthermia may be seen in pontine haemorrhage, intracranial infections, heat stroke and anticholinergic drug toxicity.

RECOGNITION OF BRAIN HERNIATION

When patients with an impaired level of consciousness deteriorate, it is important to consider brain herniation as a possible cause of the worsening. Several herniation syndromes have been described Subfalcine herniation usually results from the lateral displacement of the brain and is identified by the horizontal shift of the pineal gland. Ischaemia of the medial aspect of the cerebral hemispheres can result from compression of the pericallosal and the marginal arteries. Transtentorial herniation results from the downward displacement of the upper brainstem (central herniation) with or without involvement of the uncus (lateral herniation). The clinical signs of a central herniation are progressive obtundation, Cheyne–Stokes respiration, small pupils followed by extensor posturing and medium-sized fixed dilated pupils. Uncal herniation differs from central herniation in that pupillary dilatation occurs early in the process because of third-nerve compression. The traditional Cushing's response of hypertension and bradycardia is not always a feature of herniation and any heart rhythm may be present. Tonsillar herniation is the protrusion of the cerebellar tonsils through the foramen magnum, resulting in caudal medullary compression and obstruction of the fourth ventricle.

DIFFERENTIATING TRUE COMA FROM PSEUDOCOMA

Patients feigning coma resist passive eye opening and may even hold their eyes tightly closed. They may blink in response to a threat and do not demonstrate spontaneous roving eye movements. In contrast, they move the eyes concomitantly with head rotation and with cold caloric testing they may wake up or demonstrate preservation of the fast component of nystagmus. They also demonstrate avoidance of 'self-injury'. In addition, the pattern of clinical 'abnormalities' does not fit any specific neurological syndromes.

MANAGEMENT OF THE COMATOSE PATIENT

EMERGENT THERAPEUTIC MEASURES

Irrespective of the aetiology of coma, certain emergent therapeutic measures apply to the care of all patients. These take precedence over any diagnostic investigation.

1. Ensure adequate airway and oxygenation.
2. Secure intravenous access and maintain circulation.
3. Administer 50% dextrose after drawing a sample of blood for serum glucose levels. Although there are theoretical concerns about augmentation of brain lactic acid production[14,15] in anoxic coma, the relatively good prognosis for hypoglycaemic coma when treated expeditiously far outweighs any potential risks of glucose administration.
4. Thiamine must always be administered in conjunction with dextrose to prevent precipitation of Wernicke's encephalopathy.

5. Consideration should be given to administering naloxone, when there is a suspicion of narcotic overdose with impending respiratory arrest.
6. If hypertension, bradycardia and fixed dilated pupils are present at the time of the initial presentation, suggestive of marked intracranial hypertension and tentorial herniation, 20% mannitol at a dose 0.5–1 g/kg body weight should be administered. Consideration should be given to the emergency placement of an external ventricular drain.
7. Treat suspected meningitis with antibiotics even if CSF results are not available. A combination of penicillin and ceftriaxone is usually recommended for a community-acquired bacterial meningitis.
8. Control of seizures must be achieved as outlined in the chapter on status epilepticus.
9. Treat extreme body temperatures.
10. Stabilisation of the cervical spine if trauma is suspected.

INVESTIGATIONS

The order of investigation depends on the clinical circumstance. In the majority of cases, history and examination will provide enough information to be able to perform specific cause-related investigation. In general, the investigations can be grouped as follows.

ROUTINE INVESTIGATIONS

Measurements of serum glucose, electrolytes, arterial blood gases, liver and renal function tests, osmolality, and blood count and blood film are part of the routine investigations. When drug overdose is suspected a toxicology screen for alcohol, paracetamol, salicylates, benodiazepines and tricyclic antidepressants should be performed. A sample of serum should be stored for later analysis for uncommon drug ingestions.

NEUROIMAGING

CT SCAN

The most commonly used radiological investigation for evaluation of the comatose patient is computerised tomography (CT) scan of the brain. This is useful for diagnosing CNS trauma, subarachnoid (SAH) and intracerebral haemorrhage, haemorrhagic and non-haemorrhagic strokes, cerebral oedema, hydrocephalus and the presence of a space-occupying lesion (SOL). Frequently a CT is performed prior to a lumbar puncture to exclude rather than confirm the presence of severe cerebral oedema or a SOL. Its other advantages include lower cost, easy availability, short examination time and safety in the presence of pacemakers, surgical clips and other ferromagnetic substances. The advent of helical CT whereby multiple images are possible has reduced scanning times and is suitable for the uncooperative patient. The limitations of a CT scan include:

- the need to transfer the patient to a site where resuscitation and monitoring facilities are limited
- the need to sedate and possibly endotracheally intubate patients who are agitated
- its low sensitivity to demonstrate an abnormality in the acute phase of a stroke
- its low sensitivity for detecting brainstem lesions
- the need to administer i.v. contrast agents: the two major side-effects of i.v. contrast include anaphylaxis (with an approximate death rate of 1 in 40 000) and renal failure. The use of *N*-acetylcysteine, sodium bicarbonate and haemodialysis has been reported to reduce the incidence of contrast-induced nephropathy, although data in critically ill patients are minimal[16]. There are a series of CT images (Figs 42.1 to 42.12) available at Excon site under 'Ancillary' tab.

MAGNETIC RESONANCE IMAGING (MRI)

MRI scans provide superior contrast and resolution of the grey and white matter compared with CT scans, thus facilitating easy identification of the deep nuclear structures within the brain. MRI is more sensitive than CT for the detection of acute ischaemia, diffuse axonal injury, and cerebral oedema, tumour and abscess. Brainstem and posterior fossa structures are better visualised. The other advantage of MRI is the use of non-ionising energy. The use of gadolinium, a paramagnetic agent, as a contrast agent permits sharp definition of lesions. MR coupled with angiography (MRA) may enable diagnosis of vascular lesions. MRI is, however, limited by:

- the need for special equipment
- long imaging times
- the need to transfer the patient to a site where resuscitation and monitoring facilities are limited
- the need to sedate and possibly endotracheally intubate patients who are agitated
- risk of dislodgement of metal clips on blood vessels and resetting of pacemakers. MRI images are better for the detection of ischaemia, cerebral oedema, diffuse axonal injury and abscess. They can also be used to see vasculature. Examples can be seen on Figures 42.11 to 42.13 available at Excon site under 'Ancillary' tab.

PET AND SPECT SCANS

Newer nuclear medicine scans such as SPECT (single photon emission with computerised tomography) and PET (positron emission tomography) are useful for the assessment of cerebral blood flow and oxygenation and in the prognostication of neurotrauma, but have little role to play in the management of acute disorders of consciousness. In PET scans, positron-emitting isotopes such as ^{11}C, ^{18}F and ^{15}O are incorporated into biologically active compounds such as deoxyglucose or fluoro-deoxyglucose, which are metabolised in the body. By determining the concentration of the various

tracers in the brain and constructing tomographic images, cerebral blood flow and metabolism can be measured by PET scanning.

SPECT scans use iodine-containing isotopes incorporated into biologically active compounds and, like PET scans, their cranial distribution is determined after a dose of tracer. Information on cerebral blood flow and metabolism can be obtained from SPECT scans. The advantage of a PET scan is that it does not require a cyclotron for the generation of isotopes. Despite their many advantages, both these technologies continue to be research tools and are not routinely available in many medical centres.

LUMBAR PUNCTURE (LP)[17]

Cerebrospinal fluid is most commonly obtained by means of a lumbar puncture. This should be performed after ensuring that raised intracranial pressure has been excluded clinically or radiologically. The major use of a lumbar puncture is to diagnose an intracranial infection and to detect abnormal cytology in cases of suspected malignant meningeal infiltration. The advent of CT scans has diminished the role of LP in the diagnosis of SAH. Some of the commonly reported complications post lumbar puncture include post-puncture headache (12–39%) and traumatic tap (15–20%). Brain herniation is a rare potential complication seen with conditions associated with raised intracranial pressure due to a space-occupying lesion.

EEG IN COMA[18–20]

The usefulness of EEG in coma is summarised in **Box 49.2**. Continuous EEG monitoring in the ICU has been reported to be useful in the identification of acute cerebral ischaemia and non-convulsive seizures and for monitoring therapy used in induced coma, such as thiopentone infusion for refractory status, and to assess level of sedation.

Box 49.2 Usefulness of EEG in coma

Identification of non-convulsive status epilepticus
Diagnosis of hepatic encephalopathy
- presence of paroxysmal triphasic waves

Assessing severity of hypoxic encephalopathy
- presence of theta activity
- diffuse slowing
- burst suppression (seen with more severe forms)
- alpha coma (seen with more severe forms)

Herpes encephalitis
- periodic sharp spikes

Monitoring of therapy (e.g. thiopentone infusion for status epilepticus)

EVOKED POTENTIALS

Visual, brainstem and somatosensory evoked potentials test the integrity of neuroanatomical pathways within the brain and the spinal cord. They may be used in the diagnosis of blindness in comatose patients and in the assessment of locked-in states. There are data to suggest that they have better prognostic value than clinical judgement in patients with anoxic coma.[21–22]

BIOCHEMICAL ABNORMALITIES[23–26]

A number of biomarkers of brain injury have been evaluated as predictors of severity of brain injury and to assess progression of injury severity from traumatic and non-traumatic aetiologies. These include neuron-specific enolase (cytoplasm of neurons), S-100B protein (astroglial cells), CK-BB fraction (astrocytes), glial fibrillary acidic protein (glial origin), calpain and caspase. Although early studies showed S-100B as a reliable marker of traumatic brain injury, concerns remain about their sensitivity and specificity for assessment of severity and prediction of outcome.

CARE OF THE COMATOSE PATIENT

AIRWAY

As mentioned before, assessment of airway adequacy should take precedence over any diagnostic investigation in comatose patients. This is best done by assessing the patient's response to command and physical stimulation, and whether a gag reflex is present. Securing the airway will depend on the level of consciousness. This may entail simple manoeuvres such as jaw thrust, chin lift, use of oropharyngeal airways or, in the comatose patient, mandate endotracheal intubation. All of these patients are at risk of pulmonary aspiration and there must be a low threshold for establishing a definitive airway.

As a general rule, patients presenting with medical causes of coma may be nursed on their side (coma position) if the airway is adequate. However, all traumatised patients should be assumed to have a potential cervical spine injury and must be nursed with the cervical spine in the neutral position and/or with a rigid collar until an injury is excluded by definitive radiological views. All patients with disordered consciousness must receive supplemental oxygen.

VENTILATION

It is important to ensure optimal gas exchange and avoid hypoxia and hypercapnia. Generally a Pa_{O_2} of >80 torr (10.66 kPa) and P_{CO_2} of 35–40 torr (4.66–5.33 kPa) is desirable. If spontaneous ventilatory efforts are not adequate to achieve these levels of arterial blood gases, mechanical ventilatory support may be necessary.

CIRCULATION

Adequacy of circulation should be assessed by conventional clinical end-points. The goals of circulatory therapy in coma include prompt restoration of appropriate mean arterial blood pressure, correction of dehydration and hypovolaemia and urgent attention to life-threatening causes of shock.

SPECIFIC TREATMENT

This will depend on the underlying aetiology of the coma and is discussed in the relevant chapters. Avoidance of secondary insults is of paramount importance in the management of these patients.[27,28]

NURSING CARE

Meticulous eye and mouth care, regular changes in limb position, limb physiotherapy, bronchial toilet and psychological support are mandatory. Nosocomial infections and iatrogenic complications are associated with an increased mortality and morbidity in these patients and must be promptly diagnosed and treated. The rational use of daily investigations, invasive procedures and antibiotic prescription is essential.

OTHER THERAPY

Stress ulcer and deep vein thrombosis prophylaxis should be instituted. Early establishment of enteral feeding via a nasoenteric tube is preferable. It is important to exclude a basal skull fracture before insertion of a nasoenteric tube.

ANOXIC COMA/ENCEPHALOPATHY

Cardiac arrest is the third leading cause of coma resulting in ICU admission after trauma and drug overdose. The symptomatology and clinical outcome of patients with anoxic brain damage depend on the severity and duration of oxygen deprivation to the brain. A number of criteria have been developed to prognosticate outcome in anoxic coma. Although a number of laboratory and imaging criteria contribute to the prognostic assessment, clinical signs still have major prognostic impact. The important clinical predictors of outcome are listed in **Table 49.6**. However, there are data to suggest that electrophysiological studies using evoked potentials have far greater prognostic accuracy compared with clinical assessment.[29] It is important to note that the clinical criteria of poor prognosis were developed in the pre-hypothermia era. The optimal time for prognostication following hypothermia is unclear.[30]

Table 49.6 Clinical and laboratory predictors of unfavourable prognosis in anoxic coma[21,29,53]

CLINICAL PREDICTOR	UNFAVOURABLE PROGNOSIS
Duration of anoxia (time interval between collapse and initiation of CPR)	8–10 min
Duration of CPR (time interval between initiation of CPR and ROSC)	>30 min
Duration of postanoxic coma	>72 hours
Pupillary reaction	Absent on day 3
Motor response to pain (absent=a motor response worse than withdrawal)	Absent on day 3
Roving spontaneous eye movements	Absent on day 1
Elevated neuron-specific enolase	>33 μg/L
SSEP recording	Absent N20

Box 49.3 Aetiology of metabolic/toxic encephalopathy[54–56]

Hepatic failure
Renal failure
Respiratory failure
Sepsis
Electrolyte abnormalities: hyponatraemia, hypernatraemia, hypercalcaemia
Hypoglycaemia and hyperglycaemia
Acute pancreatitis
Endocrine – Addisonian crisis, myxoedema coma, thyroid storm
Drug withdrawal – benzodiazepine, opiates
Hyperthermia
Toxins: alcohols, glycols, tricyclic antidepressants
ICU syndrome
D-lactic acidosis

THE CONFUSED/ENCEPHALOPATHIC PATIENT IN THE ICU

Encephalopathy is a term used to describe the alteration in the level or content of consciousness due to a process extrinsic to the brain. Metabolic encephalopathy, particularly of septic aetiology, is the most common cause of altered mental status in the ICU setting.[31,32] A number of processes can lead to metabolic encephalopathy (**Box 49.3**). A number of features in the history and examination help to differentiate metabolic from structural causes of altered conscious states (**Table 49.7**).

Owing to their increased frequency in and exclusiveness to the critical care setting, two types of encephalopathy will be considered in detail: septic encephalopathy and ICU syndrome.

Table 49.7 Distinguishing features of structural and metabolic encephalopathy[56]

FEATURE	STRUCTURAL	METABOLIC
State of consciousness	Usually fixed level of depressed conscious state, may deteriorate progressively	Milder alteration of conscious state, waxing and waning of altered sensorium
Fundoscopy	May be abnormal	Usually normal
Pupils	May be abnormal, either in size or response to light	Usually preserved light response (although pupil shape and reactivity affected in certain overdoses – see above)
Eye movements	May be affected	Usually preserved
Motor findings	Asymmetrical involvement	Abnormalities usually symmetrical
Involuntary movements	Not common	Asterixis, tremor, myoclonus frequently seen

Sepsis-associated encephalopathy (SAE) has been reported to occur in 8–80% of patients with sepsis.[33] The criteria to diagnose SAE include presence of impaired mental function, evidence of an extracranial infection and absence of other obvious aetiologies for the altered conscious state. Although the precise mechanism of damage to the brain has not been delineated, the pathogenesis of the encephalopathy is thought to be multifactorial: alteration in cerebral blood flow induced by mediators of inflammation, generation of free radicals by activated leucocytes resulting in erythrocyte sludging in the microcirculation, breakdown of the blood–brain barrier resulting in cerebral oedema, reduced brain oxygen consumption induced by endotoxin and cytokines, neuronal degeneration and increased neuronal apoptosis, increases in aromatic amino acids resulting in altered neurotransmitter function and increased GABA-mediated neurotransmission leading to general inhibition of the CNS. Hypotension may contribute to the encephalopathy.[34,35] The asterixis, tremor and myoclonus – features of other metabolic encephalopathies – are uncommon in sepsis. The presence of lateralising signs is extremely rare in SAE and warrants exclusion of other causes such as stroke. The mortality of patients with SAE is higher than in those with sepsis without encephalopathy.[36] Therapy is largely directed at the underlying septic process.

ICU ENCEPHALOPATHY OR ICU SYNDROME[37,38]

This is a term used to describe behavioural disorders that develop in patients 5–7 days after admission to intensive care. Clinically this may present as agitation, restlessness and frank delirium. The causes are multifactorial: prolonged ventilation, sleep deprivation,[39,40] distortion of perception with loss of day–night cycles, immobilisation, noisy environment and monotony. These coupled with administration of multiple sedatives and neurological consequences of the underlying disease can precipitate psychotic behaviour in the ICU. It is important to bear in mind that *this is a diagnosis of exclusion and that all other reversible causes are looked for (see* Box 49.2*)* before this diagnostic label is applied. Tools to assess delirium such as the CAM-ICU have been developed and validated for the critical care setting.[41]

Abnormal behaviour can increase patient morbidity (self-extubation, ripping of catheters, soft tissue damage, etc.). Episodes of delirium in the ICU are also associated with increased mortality.[42] Postoperative delirium after cardiac surgery has also been associated with a significant decline in cognitive ability during the first year after cardiac surgery.[43] It is important to identify the underlying cause of the abnormal behaviour to institute appropriate therapy. Management of this condition may require the use of restraints, sedation and major tranquillisers. Improvement of sleep quality (minimising interruption of nocturnal sleep, adjusting lighting in the ICU), reducing patient boredom by the use of television and music and better communication with the patient may reduce the incidence and severity of this syndrome. Dexmedetomidine has been advocated as an agent to minimise delirium in the critically ill patient.[44]

PROGNOSIS IN COMA

Drug-induced comas usually have a good prognosis unless hypoxia and hypotension have resulted in severe secondary insults. Coma following head injury has a statistically better outcome compared with non-traumatic coma (coma occurring during the course of a medical illness). In non-traumatic coma lasting for 6 hours or greater, only 15% of the patients make a meaningful recovery to be able to return to their pre-morbid state of health.[45] The prognosis following anoxic coma has been described in a separate section. Within the non-traumatic coma category, coma resulting from infection, metabolic causes and multiple organ dysfunction syndrome have better outcome compared with anoxic coma.[46] A number of outcome scales have been developed to assess neurological recovery following brain injury.[47] These include the Barthel Index, Rankin Scale and the Glasgow Outcome Scale (GOS). The GOS is widely used to assess recovery after traumatic brain

injury. It has five broad categories: 1=good recovery, 2=moderate disability, 3=severe disability, 4=persistent vegetative state and 5=death. It is simple, easy to administer and has been reported to have good inter-rater agreement.

TREATMENT OPTIONS IN DISORDERS OF CONSCIOUSNESS

No effective standardised treatment exists for these patients. Currently evaluated interventions can be divided into pharmacological and non-pharmacological measures. Pharmacological measures include the use of levodopa and amantadine. Initiial trials reported some recovery response in terms of reduction in spasticity and improved cognitive behaviour and communication such as following simple commands. Zolpidem has also been trialled in patients with traumatic and anoxic aetiologies of reduced consciousness and results have been variable. Although some investigators report enhanced verbal, motor and cognitive functions, these have not been reproduced in other small trials. Moreover, the duration of effect of zolpidem is short. Bromocriptine and intrathecal baclofen have also been tried, but no large-scale studies have been reported.

Non-pharmacological measures include deep brain stimulation, extradural cortical stimulation, spinal cord stimulation and median nerve stimulation. Although reports of improved responsiveness have been published, the evidence is largely anecdotal and data from large studies are lacking.

Status epilepticus

Helen I Opdam

Status epilepticus (SE) is a medical emergency requiring prompt intervention to prevent the development of irreversible brain damage.

DEFINITION AND CLASSIFICATION

The duration of seizure activity required to define SE has not been universally agreed upon. Most authors have defined SE as more than 30 minutes duration of either a single seizure, or intermittent seizures with no regaining of consciousness between seizures.[1–4] This definition is most useful for epidemiological research[5] and is based on experimental studies that show irreversible neuronal damage occurs after 30 minutes of seizure activity.[6]

There is general acceptance of an operational definition of SE as 5 minutes of continuous seizure activity, or two or more discrete seizures with no intervening recovery of consciousness. It has arisen from the need to rapidly initiate treatment for SE and the observation that seizures persisting beyond this duration are unlikely to remit spontaneously.[7] Promulgation of this definition and resultant earlier treatment may be responsible for a decline in the incidence of SE.[5]

Refractory SE is defined as failure of initial therapy, such as benzodiazepines and phenytoin, usually necessitating treatment with agents that induce general anaesthesia.[8–10] Refractory SE develops in about one in five patients presenting with an SE episode and is associated with a worse prognosis.[9,11]

Continuation or recurrence of SE beyond 24 hours of anaesthetic therapy has been termed ‘super-refractory SE’.[12]

SE is commonly separated into two categories:

- *Generalised convulsive SE (GCSE):* seizures are primary or secondarily generalised and the patient has generalised tonic and/or clonic convulsive movements with loss of consciousness.
- *Non-convulsive SE (NCSE):* there is altered consciousness and electroencephalography (EEG) evidence of seizures without convulsive movements. NCSE is a heterogeneous disorder with multiple subtypes. NCSE may evolve from GCSE when electrical seizure activity continues with loss of motor manifestations.

The incidence of SE is U-shaped, being greatest under 1 year and over 60 years of age.[5]

PATHOPHYSIOLOGY

Ongoing or recurrent seizures result from failure of normal seizure terminating mechanisms and predominance of excitation causing seizure activity to persist. The major inhibitory mechanism in the brain is γ-aminobutyric acid A ($GABA_A$) receptor-mediated inhibition. With ongoing seizure activity $GABA_A$ receptors undergo cellular internalisation and subsequent degradation, leading to loss of endogenous inhibition and sustainability of seizures. This reduction in synaptic $GABA_A$ receptors explains the progressive pharmacoresistance to GABAergic anticonvulsants such as benzodiazepines.[13]

Excitatory mechanisms are predominantly via glutamine acting on *N*-methyl-D-aspartate (NMDA) receptors. NMDA receptors increase on synapses during ongoing epileptic activity, facilitating neuronal excitability and persistence of seizures. This in contrast explains the efficacy of NMDA antagonists, even late in the course of SE.

The pathophysiological effects of seizures on the brain are thought to result from both direct excitotoxic neuronal injury and secondary injury due to systemic complications such as hypotension, hypoxia and hyperthermia. Ongoing excitation leads to neuronal injury and death, predominantly through mitochondrial dysfunction. Experimental models and anecdotal human evidence suggest also that SE is epileptogenic, although the mechanisms of this are not well understood.[13]

AETIOLOGY

Status epilepticus may occur de novo (approximately 60% of presentations) or less commonly in a previously diagnosed epileptic.[5] In the situation where refractory SE does not have a clear cause, more unusual conditions should be considered as their diagnosis may lead to a specific therapy. These include autoimmune conditions, mitochondrial diseases and unusual infections.[14] The aetiologies of SE are given in **Box 50.1**.[2,5,14,15]

Box 50.1 Causes of status epilepticus in adults[2,4,14,15]

Low antiepileptic drug levels – poor compliance, recent dose reduction or discontinuation (most common cause in patients with epilepsy)
Stroke – vascular occlusion or haemorrhage
Metabolic disturbances – electrolyte abnormalities (hyponatraemia, hypocalcaemia, hypomagnesaemia, hypophosphataemia), hyperglycaemia, hypoglycaemia
Organ failure – uraemia, hepatic encephalopathy
CNS infection – bacterial meningitis, viral encephalitis, cerebral toxoplasmosis, tuberculosis, other
Cerebral hypoxia/anoxia
Alcohol – withdrawal or intoxication
Head trauma
Drug toxicity – cephalosporins, isoniazid, tranexamic acid, tacrolimus, cyclosporine, tricyclic antidepressants, olanzapine, phenothiazines, theophylline, cocaine, amphetamine, antiepileptic drugs, other
CNS tumours – primary or secondary
Temporally remote causes (previous CNS injury) – stroke, trauma, tumour, meningitis
Hypertensive encephalopathy, eclampsia
Immunological disorders – paraneoplastic syndromes, Hashimoto's encephalopathy, anti-NMDA receptor encephalitis (may have associated ovarian tumour), cerebral lupus, thrombotic thrombocytopenic purpura, other
Mitochondrial diseases

GENERALISED CONVULSIVE STATUS EPILEPTICUS (GCSE)

GCSE is the most common and most dangerous type of SE and accounts for approximately 75%.[2] It encompasses a broad spectrum of clinical presentations, from overt generalised tonic–clonic seizures to subtle convulsive movements in a profoundly comatose patient.[16]

CLINICAL

Typically, early in the evolution of seizures, patients are unresponsive with obvious tonic (sustained contractions) and/or clonic (rhythmic jerking) movements (overt GCSE). Motor manifestations may be symmetrical or asymmetrical.

With time, the clinical manifestations may become subtle, and patients have only small-amplitude twitching movements of the face, hands, or feet, or nystagmoid jerking of the eyes (late or subtle GCSE).[16]

Later still some patients will have no observable repetitive motor activity and the detection of ongoing seizures requires EEG (electrical GCSE). Most authors classify this as a form of NCSE.[7,17] Such patients are still at risk of CNS injury and require prompt treatment.

EEG CHANGES

Just as there is a progression from overt to increasingly subtle motor manifestations, there is also a predictable sequence of EEG changes during untreated GCSE. Initially, discrete electrographic seizures merge to a waxing and waning pattern of seizure activity, followed by continuous monomorphic discharges, which become interspersed with increasing periods of electrographic silence and, eventually, periodic epileptiform discharges on a relatively flat background.[16] The presence of any of these EEG patterns should suggest the diagnosis of GCSE.

Box 50.2 Physiological changes in generalised convulsive status epilepticus[18]

Hypoxia
Respiratory acidosis
Lactic acidosis
Hyperpyrexia
Hypertension (early)/hypotension (late)
Hyperglycaemia (early)/hypoglycaemia (late)
Tachycardia
Cardiac arrhythmias
Blood leucocytosis
CSF pleocytosis, increased CSF protein
Intracranial hypertension
Neurogenic pulmonary oedema
Aspiration pneumonitis
Rhabdomyolysis

ENDOCRINE AND METABOLIC EFFECTS

Early in GCSE there is a marked increase in plasma catecholamines, producing systemic physiological changes that resolve if SE is stopped early (**Box 50.2**). However, if seizures continue, many of these early physiological changes reverse and the resultant hypotension and hypoglycaemia may exacerbate neurological injury.[18]

Hyperthermia is due to both muscle activity and central sympathetic drive, and thus may still occur when paralysing agents prevent motor activity. In early SE, both cerebral metabolic activity and cerebral blood flow (CBF) are increased. In late SE, although cerebral metabolic activity remains high, CBF may fall owing to hypotension and loss of cerebral autoregulation leading to cerebral ischaemia.

PSEUDOSEIZURES

An important differential diagnosis of generalised convulsive epilepsy is pseudoseizures.[19] These can occur in patients with or without a history of epilepsy. Clinical features suggestive of pseudoseizures are listed in **Box 50.3**. "Distinction between the two may be extremely difficult, and can be made with complete certainty only using EEG monitoring." Pseudostatus, misdiagnosed as true SE, is often refractory to initial therapy and can lead to patients receiving general anaesthesia and mechanical ventilation.

Box 50.3 Features suggestive of pseudoseizures

- Lack of stereotyped seizures, with behavioural manifestations varying from event to event
- Lack of sustained convulsive activity – 'on–off' appearance
- Increase in movement if restraint is applied
- Abolition of motor movements with reassurance or suggestion
- Resistance to eye opening and gaze aversion
- Poor response to treatment, refractory status epilepticus
- Absence of pupillary dilatation
- Normal tendon reflexes and plantar responses immediately after convulsion
- Lack of metabolic consequences despite some hours of apparent fitting

Box 50.4 Investigations in status epilepticus

Initial studies

- Blood glucose, electrolytes (sodium, potassium, calcium, magnesium), urea
- Arterial blood gases
- Anticonvulsant drug levels
- Full blood count
- Urinalysis

Further investigations after stabilisation

- Liver function tests, lactate, creatine kinase
- Toxicology screen
- Lumbar puncture
- Electroencephalogram
- Brain imaging with computed tomography or magnetic resonance imaging

NON-CONVULSIVE STATUS EPILEPTICUS (NCSE)

This accounts for approximately 25% of SE, though its incidence is probably underestimated because of failure to recognise and diagnose the condition.

The diagnosis of NCSE generally requires a change in behaviour and/or responsiveness from baseline for at least 30 minutes, no overt seizure activity and an EEG with epileptiform discharges.[20] A response to intravenous antiepileptic drugs (e.g. benzodiazepines), with clinical improvement and resolution or improvement in EEG epileptic activity, is helpful in confirming the diagnosis.[21]

The diagnosis of NCSE should be considered in any patient with an unexplained altered conscious state, particularly those with CNS injury, metabolic disturbance, hepatic encephalopathy or sepsis. Series where EEG has been performed in critically ill patients with an unexplained depressed conscious state have found a high incidence of NCSE (8–18%).[22–24] EEG monitoring is required in patients with GCSE who do not recover consciousness after resolution of overt convulsive activity; in one study more than 14% of such patients had NCSE.[17]

NCSE is a heterogeneous disorder with multiple subtypes and published reports often describe diverse cohorts of patients. Although attempts have been made to define and classify this disorder, there is yet no universally accepted definition or classification.[20,25]

Traditionally NCSE is divided into absence status epilepticus (ASE) and complex partial status epilepticus (CPSE).[21] ASE is associated with bilateral diffuse synchronous seizures and may be 'typical' as characterised by generalised 3 Hz spike-wave EEG activity during periods of altered behaviour, or responsiveness that occurs in children with idiopathic generalised epilepsy who are otherwise normal.[21] Atypical ASE is a heterogeneous syndrome occurring in patients with mental retardation and epilepsy with multiple seizure types.

CPSE may present with a wide variety of clinical features and a variable degree of impairment of consciousness, which includes confusion, agitation, bizarre or aggressive behaviour and coma.[20] More recently other possible classification systems have been proposed.[20,25–27]

The most important factor in determining outcome in NCSE is the underlying cause.[4,20,21]

NCSE is often mistaken for other conditions, resulting in a delay in diagnosis and treatment. A high index of suspicion must therefore be present to trigger investigation with an EEG.

The differential diagnosis of NCSE includes:

- metabolic encephalopathy
- drug intoxication
- cerebrovascular disease
- psychiatric syndromes (dissociative reactions, acute psychosis)
- post-ictal confusion.

EPILEPTIFORM ENCEPHALOPATHIES

In many advanced coma stages, the EEG exhibits continuous or periodic EEG abnormalities, but in such situations it is unclear whether the abnormal discharges are responsible for, or contribute to, the altered consciousness or are merely a reflection of a severe cerebral insult.[27]

Some consider myoclonic SE that follows an anoxic insult as part of this category, rather than as a form of NCSE.[27]

INVESTIGATIONS

Not all of the investigations listed in **Box 50.4** need to be performed in every patient. The selection of tests depends on both the patient's history and the presentation.

NEUROIMAGING

Most patients with SE should have a computed tomography (CT) scan of the brain performed, although this

may not always be necessary if another episode of SE occurs in a patient with established epilepsy who has previously been thoroughly evaluated. Magnetic resonance imaging (MRI) may occasionally reveal abnormalities not visualised on CT scans and should be considered for non-emergency imaging. Imaging should be performed only after control of SE and patient stabilisation.[28]

LUMBAR PUNCTURE

In any patient, especially in young children with fever and SE, CNS infection and lumbar puncture along with blood cultures should be considered.[29] Meningitis is an uncommon cause of SE in adults and, unless the suspicion of CNS infection is high, brain imaging should be performed before a lumbar puncture. Contraindications to lumbar puncture include intracranial hypertension, mass lesion and hydrocephalus. If meningitis is suspected and a lumbar puncture cannot be performed expediently, antibiotics should be administered immediately rather than delayed. Approximately 20% of patients have a modest CSF white cell count pleocytosis after SE and such patients should be treated for suspected meningitis until the diagnosis is excluded.[1]

MANAGEMENT

GENERALISED CONVULSIVE STATUS EPILEPTICUS (GCSE)

An accurate history should be obtained, with particular emphasis on eye-witness accounts of the onset and nature of the seizures, and a full physical examination performed. However, neither should delay initial emergency management. Rapid control of seizures is crucial to prevent brain injury and the development of refractory SE. There is evidence that the longer SE goes untreated the harder it is to control with drugs.[8,9,30,31]

Management of SE involves termination of seizures, treating precipitating causes and underlying conditions, and prevention of complications and recurrence of seizures.

Few controlled data are available to support the use of any particular agents. One of the few randomised, double-blind clinical trials for treatment of GCSE found that lorazepam, phenobarbital or diazepam followed by phenytoin are all acceptable as initial treatment, but that phenytoin alone was not as effective as lorazepam.[31] Another randomised controlled trial in the pre-hospital setting found intravenous lorazepam and diazepam to be equally effective and superior to placebo in terminating GCSE.[32]

There are few data to guide the treatment of refractory SE, for which anaesthetising agents such as thiopental, propofol or midazolam infusions are commonly used. A randomised controlled trial of propofol versus barbiturates was terminated after 3 years with only 24 of the required 150 patients recruited.[33]

The EEG goal of treatment for refractory SE remains controversial, with some advocating EEG background suppression (isoelectric) and others suppression of seizures regardless of the EEG background activity.[7,9,10,34]

Various protocols for SE management have been suggested.[1,7,9,34] One approach is outlined in **Box 50.5**.

NON-CONVULSIVE STATUS EPILEPTICUS (NCSE)

Patients with NCSE are a heterogeneous group and as such there is a variable response to treatment.[25] Prognosis is most closely related to the underlying aetiology.[20,21]

Clinical response to intravenous benzodiazepine is predictive of a good outcome.[35]

There is considerable debate as to whether NCSE presents the same degree of risk of neurological injury as GCSE.[36] Prompt treatment is generally recommended and the use of additional non-anaesthetising anticonvulsants, such as levetiracetam, phenobarbital and valproate, has been suggested prior to embarking upon general anaesthesia.[7,21,37]

The potential side-effects of aggressive treatment (hypotension, immunosuppression) need to be balanced against the potential neurological morbidity of NCSE.[38] Particularly in elderly patients, aggressive treatment and anaesthesia may be associated with more risk than benefit and result in a worse outcome.[20,38,39]

DRUGS FOR STATUS EPILEPTICUS

BENZODIAZEPINES

Benzodiazepines are fast-acting antiseizure drugs and are therefore preferred as initial therapy. They act mainly by enhancing the neuroinhibitory effects of γ-aminobutyric $acid_A$ ($GABA_A$). The efficacy of benzodiazepines diminishes with duration of SE as a result of a reduction in synaptic $GABA_A$ receptors with prolonged seizures.[13]

Diazepam is a highly lipid-soluble drug with rapid CNS penetration, but then redistribution resulting in a short duration of action. It can be administered either intravenously or by the rectal route. Rectal administration can be achieved using a specially formulated rectal gel, or the intravenous preparation can be diluted with an equal amount of saline and flushed into the rectum. Rectal administration should be considered when vascular access is delayed and may be particularly useful in the pre-hospital setting.

Lorazepam has a longer duration of action and has a lower incidence of seizure recurrence when used as a single agent.[31] A double-blind, randomised comparison of intravenous diazepam, lorazepam and placebo in SE in the pre-hospital setting found both benzodiazepines to be associated with greater cessation of seizures and lower requirement for intubation than placebo. There

Box 50.5 Protocol for management of SE

1. Assess A, B, C, GCS
2. Give O_2 and consider need for intubation/ventilation
3. Monitor blood pressure, ECG, pulse oximetry
4. Obtain i.v. access and draw blood for investigations
5. If patient is hypoglycaemic, or if blood glucose estimation is not available, give glucose:
   adults: give thiamine 100 mg i.v. and 50 mL of 50% glucose i.v.
   children: give 2 mL/kg of 25% glucose i.v.
6. Seizure control:
   A. Give benzodiazepine,* for example:
      diazepam: 0.2 mg/kg i.v. at 5 mg/min up to total dose of 20 mg;
      lorazepam: 0.1 mg/kg i.v. at 2 mg/min up to total dose of 10 mg;
      clonazepam: 0.01–0.02 mg/kg i.v. at 0.5 mg/min up to total dose of 4 mg.
      If diazepam stops the seizures, phenytoin should be given next to prevent recurrence.
      Repeat dose every 2–5 min if required. Note: risk of respiratory depression with cumulative doses.
   B. If seizures persist, give phenytoin:
      phenytoin: 15–20 mg/kg (adults ≤50 mg/min; children ≤1 mg/kg/min) or fosphenytoin 15–20 phenytoin equivalents (PE) mg/kg i.v. (adults ≤150 mg/min; children ≤3 mg/kg per min).
      Additional doses of 5 mg/kg i.v., to a maximum dose of 30 mg/kg can be given for persistent seizures.
      Monitor blood pressure and the ECG during infusion. If hypotension or arrhythmias develop, stop or slow the rate of the infusion.
   C. If seizures persist (refractory SE), intubate and ventilate patient. Give either:
      thiopental: slow bolus 3–5 mg/kg i.v., followed by infusion 1–5 mg/kg per h, *or*
      propofol: slow bolus 1–2 mg/kg i.v., followed by infusion 2–5 mg/kg per h,† *or*
      midazolam: slow bolus 0.1–0.2 mg/kg, followed by infusion 0.1–1.0 mg/kg per h.
      Titrate doses based on clinical and electrographic evidence of seizures, targeting electrographic suppression of seizures or EEG background suppression (isoelectric).
      Monitor BP and maintain normotension by reducing infusion rate and/or giving fluids/pressor agents.
   D. Insert nasogastric tube and administer usual anticonvulsant medications if patient is receiving treatment for pre-existing epilepsy.
   E. Beware of ongoing unrecognised seizures.
      Use EEG monitoring until seizures are controlled and then for 1–2 hours after seizures stop. Continue to monitor the EEG continuously, or for periods of more than 30 minutes every 2 hours, during the maintenance phase.
      Avoid muscle relaxants (use continuous EEG if giving repeated doses of muscle relaxants).
   F. Discontinue midazolam or thiopental, or start reducing propofol, approximately 12 hours after resolution of seizures. Use continuous EEG monitoring and observe for further clinical and/or electrographic seizure activity. If seizures recur, reinstate the infusion and repeat this step at 12–24-hour intervals or longer if the patient's seizures remain refractory.

   In addition:

Look for and treat cause and precipitant.††

Look for and treat complications: hypotension, hyperthermia, and rhabdomyolysis.

*If i.v. access is not obtainable, consider rectal diazepam, buccal/sublingual or intranasal or i.m. midazolam, i.m. fosphenytoin.

†High infusion rates for prolonged periods require caution.

††In refractory SE, consider giving pyridoxine for children <18 months or if isoniazid toxicity is suspected in adults.

was a trend toward lorazepam being more efficacious than diazepam.[32]

Midazolam has a short duration of action and, unlike other benzodiazepines, can be administered via intramuscular, buccal and intranasal routes. These alternative routes of administration may be more convenient, acceptable and efficacious than diazepam administered by the rectal route.[40,41] A recent study found that intramuscular midazolam was as safe and efficacious as intravenous lorazepam and resulted in faster and more reliable administration in the prehospital setting.[42]

Midazolam administered by intravenous bolus and infusion may terminate seizures when other agents have failed. It may also have fewer side effects than alternative agents available for the treatment of refractory SE.[43] A limiting factor in its use is tachyphylaxis, which may necessitate a several-fold increase in the dose to maintain seizure control.[34] There is a wide variation in recommended infusion rates, from 0.05–0.4 mg/kg per hour[7] to 0.2–2.9 mg/kg per hour.[10]

Clonazepam has a longer duration of action than diazepam and is given by intravenous bolus. Early reports suggested that it has better efficacy and fewer side-effects than diazepam, though there are no published comparisons.

PHENYTOIN

Phenytoin is useful for maintaining a prolonged antiseizure effect after rapid termination of seizures with a benzodiazepine, or when benzodiazepines fail. When used alone as initial therapy phenytoin is not as efficacious as benzodiazepines for terminating seizures.[31]

The recommended intravenous loading dose is 20 mg/kg. The common practice of giving a standard

loading dose of 1000 mg of phenytoin may provide inadequate therapy for some adults.

When phenytoin is infused at the maximal adult recommended rate of 50 mg/min, hypotension occurs in up to 50% of patients and cardiac rhythm disturbance occurs in 2%. These adverse effects are more common in older patients and those with cardiac disease and are due to the phenytoin itself as well as the propylene glycol diluent. Blood pressure and the ECG should be monitored during infusion of phenytoin and the infusion slowed or stopped if cardiovascular complications occur.

Intramuscular administration of phenytoin is not recommended as absorption is erratic and it can cause local tissue reactions.

Fosphenytoin, a new water-soluble prodrug of phenytoin, is converted to phenytoin by endogenous phosphatases.[44] Doses of fosphenytoin are expressed as phenytoin equivalents (PE). Fosphenytoin can be administered at rates of up to 150 PE mg/min, since it is not formulated with propylene glycol, allowing therapeutic serum concentrations of fosphenytoin to be attained within 10 minutes. However, this may not necessarily result in more rapid CNS penetration and onset of action.[45]

Systemic side-effects are similar for phenytoin and fosphenytoin, although reactions at the infusion site are less common with fosphenytoin.[44]

Fosphenytoin can also be administered intramuscularly, although absorption is slower than with intravenous administration, and this route should be used only when intravenous access is not possible.

SODIUM VALPROATE

There are reports of intravenous valproate being used to treat both GCSE and NCSE in adults and children. It is non-sedating and it appears to be well tolerated with few reports of hypotension or respiratory depression.[46]

It may be particularly useful as a second- or third-line drug in situations where it is not possible, or it is preferable to avoid the use of sedating anaesthetic agents and the associated requirement for intubation.[47]

An initial dose of 10 mg/kg followed by continuous infusion or divided doses up to 20-40 mg/kg daily is recommended.[7,48]

LEVETIRACETAM

Although the data are mostly uncontrolled and retrospective, there is some evidence for the use of levetiracetam as second- or third-line therapy and in situations where it is desirable to avoid intubation, such as in NCSE and treatment of the elderly.[8,37,47,49] Levetiracetam may have particular utility in controlling seizures after hypoxic brain injury.[8]

Levetiracetam may be given intravenously in bolus doses of between 1000 and 3000 mg.

BARBITURATES

Phenobarbital is a potent anticonvulsant with a long duration of action. The usual dose is 15–20 mg/kg intravenously. It has equal efficacy to benzodiazepines and phenytoin when used first-line, but may cause greater depression of respiration, blood pressure and consciousness and therefore is often used only if these agents fail. However, many would advocate alternative and more aggressive measures for treatment of refractory SE at this point as the likelihood of phenobarbital controlling seizures when these other agents have failed is small.[10]

Thiopental is an intravenous anaesthetic agent used for refractory SE. A dose of 3–5 mg/kg is usually given for intubation, followed by repeated doses of 0.5–1 mg/kg until seizures are controlled. Following bolus intravenous administration, the drug is rapidly redistributed into peripheral fat stores and an infusion of 1–5 mg/kg per hour is required for ongoing suppression of seizures. Once lipid stores are saturated the duration of action is prolonged and recovery may take hours to days. Prolonged therapy requires the use of EEG monitoring to ensure that the seizures remain suppressed and to allow titration to the lowest dose that achieves the EEG target of seizure and/or EEG background suppression. Side-effects include hypotension, myocardial depression and immunosuppression with increased risk of infection.

Pentobarbital (the first metabolite of thiopental) is available in the USA as the alternative to thiopental.

Compared with other agents used in refractory SE (midazolam and propofol), barbiturates may result in a lower frequency of short-term treatment failure and breakthrough seizures, but result in more hypotension and slower recovery from anaesthesia.[50]

PROPOFOL

Propofol (2,6-diisopropylphenol) is an anaesthetic agent that has become increasingly popular for the treatment of refractory SE. It is administered as an intravenous bolus followed by infusion and intubation and ventilation are required.

Compared with high-dose barbiturates (pentobarbital) in adult patients with refractory SE, propofol has been found to control seizures more quickly and, because of its shorter duration of action, allows earlier re-emergence from anaesthesia.[51] However, seizures tend to recur with sudden discontinuation of propofol, necessitating recommencement of the infusion and a more gradual tapering of the dose, such that both drugs ultimately may result in a similar duration of ventilation and ICU stay.[51]

There is concern that prolonged high-dose propofol use (e.g. >5 mg/kg per hour) may result in myocardial failure, hypoxia, metabolic acidosis, lipaemia, rhabdomyolysis and death (propofol infusion syndrome).[52] Early reports were in children and later adults and its

use requires caution. There are series, however, of prolonged high-dose propofol use in adults with SE without major adverse effects.[53]

NEUROMUSCULAR-BLOCKING AGENTS

Paralysis is indicated if uncontrolled fitting causes difficulty with providing adequate ventilation or severe lactic acidosis. Neuromuscular blockade should be used only if continuous EEG monitoring is available, as the clinical expression of seizure activity is abolished.

OTHER AGENTS OF POTENTIAL USE IN REFRACTORY SE

Ketamine acts as an antagonist at the NMDA receptor and may have a role in the treatment of prolonged refractory SE.[12]

Intravenous lacosamide is a new anticonvulsant drug available in intravenous and oral formulations that may be an option for treatment of established SE after failure of standard therapy, or when standard agents are considered unsuitable. Evidence exists mainly in the form of limited case series.[54]

Pregabalin appears to be an interesting option as add-on treatment in refractory NCSE and may lessen the requirement for ICU treatment.[55]

Magnesium is the drug of choice in eclamptic seizures and also is effective in seizures due to hypomagnesaemia, but there is little evidence to support its use in other forms of SE.[12]

SURGERY

Surgery has occasionally been used in refractory SE with procedures based on standard epilepsy surgery techniques. Some success has been reported with focal resections, subpial transection, corpus callosotomy, hemispherectomy and vagus nerve stimulation.[12,56]

INTENSIVE CARE MONITORING

Monitoring using ECG, intra-arterial and central venous catheters, capnography and pulse oximetry should be considered in patients with, or at risk of, cardiorespiratory compromise. Indications for EEG monitoring are listed in **Box 50.6**.[17] Cerebral function monitors are useful in titrating doses of anaesthetic agents to EEG background suppression, but may not have sufficient sensitivity to detect seizure activity. Intracranial pressure monitoring should be considered if elevated intracranial pressure is present owing to the underlying brain pathology.

Box 50.6 Indications for EEG monitoring[17]

- Refractory SE, to aid the titration of anticonvulsant anaesthetic drugs (minimizing dose and toxicity) and ensure suppression of seizure activity*
- Patients receiving neuromuscular blockade*
- Patients who continue to have a poor conscious state after apparent cessation of seizures
- Suspected non-convulsive status epilepticus in a patient with an altered conscious state
- Suspected pseudoseizures

*Continuous or regular intermittent EEG monitoring recommended.

OUTCOME

The prognosis of patients with SE is related to age, aetiology, degree of impairment of consciousness at presentation, and duration of SE.[15,57] Refractory SE is associated with a worse prognosis and very prolonged 'super-refractory' SE an even higher mortality. However, where no underlying irreversible brain damage is present, good recovery is possible even after weeks of SE.[9,12]

Children have a much lower mortality of 3%[58] whereas those aged over 65 years have a mortality rate of 30%.[3,4]

SE that is precipitated by low antiepileptic drug levels, alcohol abuse or systemic infection has a very low mortality, whereas SE secondary to an acute CNS insult such as stroke or infection has a higher mortality.[3,5] SE associated with hypoxic brain injury is most often fatal.[59] NCSE detected in comatose critically ill patients, despite recognition and treatment, has a poor outcome.[24,39]

Consequences of SE include brain damage resulting in permanent neurological deficits and also the development of focal epilepsy (epileptogenesis). Multiorgan failure and death can result from uncontrolled seizures, the underlying illness or complications of treatment.

STATUS EPILEPTICUS IN CHILDREN

Most paediatric cases of SE occur in young children, with 80% occurring in those below 4 years of age.[58] The vast majority of cases are convulsive and generalised.[28]

The distribution of causes is highly age-dependent, with febrile SE and that due to acute neurological disease (e.g. CNS infection) being more common in children under 4 years. Remote symptomatic causes and SE in a child with previously diagnosed epilepsy are more common in older children.[58] The most frequent aetiologies of SE in children are listed in **Box 50.7**.[28,29,58]

The likelihood of bacterial meningitis is much higher in febrile children presenting with a first-ever episode of SE (12%) as opposed to a brief seizure (1%) and a high index of suspicion is required to investigate and treat for meningitis.[58]

Treatment of SE in children is essentially the same as in adults.[60]

Box 50.7 Causes of status epilepticus in children[28,29,58]

Febrile – previously neurologically normal, temp. >38°C, CNS infection excluded
Acute symptomatic – meningitis, encephalitis, cerebrovascular disease, trauma, metabolic derangement, hypoxia, sepsis, drug-related
Remote symptomatic causes – previous traumatic brain injury or insult, CNS malformation, cerebral palsy
Progressive neurological conditions – tumours, degenerative, autoimmune diseases
Cryptogenic

The underlying cause is the main determinant of mortality, which is negligible for prolonged febrile seizures and 12–16% for acute symptomatic causes.[61] Similarly, the risk of subsequent epilepsy is low in neurologically normal children but higher than 50% in those with acute or remote symptomatic causes.[61]

Acute cerebrovascular complications

Bernard Riley and Thearina de Beer

Cerebrovascular disease is common and its acute manifestation, stroke, produces considerable morbidity and mortality. Stroke is defined as an acute focal neurological deficit caused by cerebrovascular disease, which lasts for more than 24 hours or causes death before 24 hours. Transient ischaemic attack (TIA) also causes focal neurology, but this resolves within 24 hours. In the UK, stroke is responsible for 9% of all deaths accounting for around 53 000 deaths per year and is the most common cause of physical disability in adults. The incidence in most developed countries is about 1–2/1000 population per year with a 42% reduction in high-income countries but a 100% increase in low- to middle-income countries in the past four decades.[1] The main causes of stroke are cerebral infarction as a consequence of thromboembolism and spontaneous intracranial haemorrhage (either intracerebral or subarachnoid haemorrhage (SAH)), causing about 85% and 15% of strokes, respectively. The main risk factors are increasing age, hypertension, ischaemic heart disease, atrial fibrillation, smoking, diabetes, obesity, some oral contraceptives and raised cholesterol or haematocrit. The manifestations of stroke are cerebral infarction (thrombosis, embolism) and intracranial haemorrhage (intracerebral haemorrhage, SAH).

PROGNOSIS IN ACUTE CEREBROVASCULAR DISEASE

Mortality after stroke averages 30% within a month, with more patients dying after SAH or intracerebral haemorrhage than after cerebral infarction, although survival to 1 year is slightly better in the haemorrhagic group. In all types of stroke about 30% of survivors remain disabled to the point of being dependent on others. Risk of stroke increases with age and very old age is an independent predictor of death.[2] Thus stroke is often accompanied by significant age-related medical co-morbidity. In the past this may have been partially responsible for a relatively non-aggressive approach to the treatment of stroke patients, so that the gloomy prognosis of stroke becomes a self-fulfilling prophecy. The challenge for intensivists is to identify those patients who are most likely to survive and not to offer aggressive therapy to those who are not. Stroke should be regarded as a medical emergency. Patients should initially be treated in a stroke unit as there is good evidence of reduction in both mortality and dependency compared with those treated in a general ward. The UK National Institute for Health and Clinical Excellence (NICE) has published guidelines aimed at ensuring early diagnosis and aggressive therapy.[3,4]

CEREBRAL INFARCTION

Infarction of cerebral tissue (ischaemic stroke) occurs as a result of inadequate perfusion from occlusion of cerebral blood vessels in association with inadequate collateral circulation. It may occur due to cerebral thrombosis or embolism.

AETIOLOGY AND PATHOLOGY

CEREBRAL THROMBOSIS

Atherosclerosis is the major cause of major arterial occlusion and most often produces symptoms if it occurs at the bifurcation of the carotid artery or the carotid syphon. Progressive plaque formation causes narrowing and forms a nidus for platelet aggregation and thrombus formation. Ulceration and rupture of the plaque exposes its thrombogenic lipid core, activating the clotting cascade. Hypertension and diabetes mellitus are common causes of smaller arterial thrombosis. Rarer causes of thrombosis include any disease resulting in vasculitis, vertebral or carotid artery dissection (either spontaneous or posttraumatic) or carotid occlusion by strangulation or systemic hypotension after cardiac arrest. Cerebral venous thrombosis, responsible for less than 1% of strokes, may occur in hypercoagulable states such as dehydration, polycythaemia, thrombocythaemia, some oral contraceptive pills, protein C or S deficiency or antithrombin III deficiency, or vessel occlusion by tumour or abscess. Cerebral infarction may also result from sustained systemic hypotension from any cause, particularly if associated with hypoxaemia.

CEREBRAL EMBOLISM

Embolism commonly occurs from thrombus or platelet aggregations overlying arterial atherosclerotic plaques,

but 30% of cerebral emboli will arise from thrombus in the left atrium or ventricle of the heart. This is very likely in the presence of atrial fibrillation, left-sided valvular disease, recent myocardial infarction, chronic atrial enlargement or ventricular aneurysm. The presence of a patent foramen ovale or septal defects allows paradoxical embolism to occur. Iatrogenic air embolism may occur during cardiopulmonary bypass, cardiac catheterisation or cerebral angiography. Embolisation may also occur as a complication of attempted coil embolisation of cerebral aneurysms or arteriovenous malformations (AVMs) after SAH.

CLINICAL PRESENTATION

In cerebral thrombosis, there is initially no loss of consciousness or headache and the initial neurological deficit develops over several hours. Cerebral embolism may be characterised by sudden onset and rapid development of complete neurological deficit. No single clinical sign or symptom can reliably distinguish a thrombotic from an embolic event.

Where infarction occurs in a limited arterial territory the clinical signs are often characteristic. The commonest site involves the middle cerebral artery, which classically produces acute contralateral brachiofacial hemiparesis with sensory or motor deficits, depending on the precise area of infarction. Infarction of the middle cerebral territory leads to a dense contralateral hemiplegia, contralateral facial paralysis, contralateral hemianopia and ipsilateral eye deviation. Dominant left-hemisphere lesions result in language difficulties from aphasia, dysphasia, dysgraphia and dyscalculia. Non-dominant right hemispheric lesions cause the patient to neglect the left side, and failure to communicate with anyone approaching from that side. In strokes involving the posterior fossa the precise pattern of symptoms depends on the arterial territories involved and the presence or absence of collaterals. The onset of symptoms such as gait disturbance, headache, nausea, vomiting and loss of consciousness may be very rapid. Venous thrombosis may occur particularly in the cerebral veins, sagittal or transverse dural sinuses, causing headache, seizures, focal neurology and loss of consciousness. Other cognitive effects of stroke include memory impairment, anxiety, depression, emotional lability, aprosody and spatial impairment. Bilateral brainstem infarction after basilar artery thrombosis may produce deep coma and tetraparesis. Pontine stroke may produce the 'locked-in' syndrome. The precise clinical presentation depends on the size of the infarcted area and its position in the brain. Vascular lesions such as carotid dissection can present with ipsilateral Horner's syndrome with facial pain, a painful Horner's from local stellate ganglion damage or if there is significant ischaemia from impaired flow or emboli, then with contralateral signs consistent with infarction.[5]

INVESTIGATIONS

A full history and examination of the patient will produce a differential diagnosis that will require specific investigations. The aim is to make the diagnosis, establish the nature, size and position of the pathology, so that correct treatment can target the effects of the primary injury, and prevent extension of the lesion or complications occurring.

BLOOD TESTS

A full blood count should be taken to look for polycythaemia, infection or thrombocythaemia. A raised erythrocyte sedimentation rate or C-reactive protein level may indicate vasculitis, infection or carcinoma, warranting further appropriate investigations. Coagulation screen should also be taken together with serum cholesterol, triglyceride and syphilis serology. Specific investigation for thrombophilia due to protein C, protein S, Leiden factor V and antithrombin III abnormalities should be undertaken in patients with venous thrombosis or patients with otherwise unexplained cerebral infarction or TIA.

ELECTROCARDIOGRAPHY

This may demonstrate atrial fibrillation or other arrhythmia, or recent myocardial infarct.

ECHOCARDIOGRAPHY

Either transthoracic or transoesophageal echocardiography (TOE) may demonstrate mural or atrial appendage thrombus as a source of embolism. TOE is more effective in detecting patent foramen ovale, aortic arteriosclerosis or dissection.

COMPUTED TOMOGRAPHY (CT) OR MAGNETIC RESONANCE IMAGING (MRI) SCANNING

These techniques are used to distinguish infarction from haemorrhage. Tumour, abscess or subdural haematoma may also produce the symptoms and signs of stroke. Ideally, the scans should be undertaken as soon as possible to exclude conditions that are treatable by neurosurgery. Early scanning is vital if interventional treatment such as thrombolysis, anticoagulation, antiplatelet therapy or surgery is planned.

The CT scan may be normal or show only minor loss of grey/white matter differentiation in the first 24 hours after ischaemic stroke, but haemorrhage is seen as areas of increased attenuation within minutes. After a couple of weeks the CT appearances of an infarct or haemorrhage become very similar and it may be impossible to distinguish them if CT is delayed beyond this time. CT angiography will often demonstrate vascular abnormalities and vasospasm but multimodal MRI, a combination of diffusion and perfusion-weighted MRI and magnetic resonance angiography (MRA), is much more sensitive in demonstrating small areas of ischaemia and targeting those patients most suitable for thrombolysis.[6] Where cerebral infarction has occurred

as a result of venous thrombosis, the best imaging technique is MRA. Other imaging techniques are appropriate to identify the source of stroke in specific areas. Any patient with a stroke or TIA in the internal carotid artery territory should have duplex Doppler ultrasonography, which may demonstrate stenosis, occlusion or dissection of the internal carotid. Where trauma is an aetiological factor reconstruction CT bone window views are required to demonstrate any site of fracture-associated vascular injury. MRA (magnetic resonance angiography) is increasingly useful for rapid diagnosis of vascular problems as can be seen in Figure 51.1.

MANAGEMENT

The UK national sentinel stroke audit in 2008 suggested that if 80% rather than 68% of the 2000 patients with ischaemic stroke studied had been managed on a stroke unit the number dead or dependent could be reduced by 69, equating to 5% of all 1300 new cases of death and dependency in a population of 1 million.[7] In general, only those patients with a compromised airway due to depressed level of consciousness or life-threatening cardiorespiratory disturbances require admission to medical or neurosurgical ICUs. In either case, attention to basic resuscitation, involving stabilisation of airway, breathing and circulation, is self-evident.

Figure 51.1 MRA. Internal carotid dissection associated with exercise, skiing the bumps. Presentation painful Horner's.

AIRWAY AND BREATHING

Patients with Glasgow Coma Scores (GCS) of 8 or less, or those with absent gag or defects of swallowing (both of which may occur at higher GCS), will require intubation to preserve their airway and prevent aspiration. Where this requirement is likely to be prolonged, early tracheostomy should be considered. Adequate oxygenation and ventilation should be confirmed by arterial blood gas analysis, and supplemental oxygen prescribed if there is any evidence of hypoxia. If hypercarbia occurs then ventilatory support to achieve normocarbia is necessary to prevent exacerbation of cerebral oedema. Mortality and poor functional outcome can be poor in patients over 65 who require mechanical ventilation with only 40% surviving for 6 months, but 25% of survivors may recover to good functional outcome and reasonable quality of life.[8] There is currently no evidence to suggest that early tracheostomy in ventilated stroke patients is of any benefit, although a randomised prospective trial of early tracheostomy versus prolonged intubation has been mooted.[9]

CIRCULATORY SUPPORT

A large number of stroke patients will have raised blood pressure on admission, presumably as an attempt by the vasomotor centre to improve cerebral perfusion. Hypertensive patients may have impaired autoregulation and regional cerebral perfusion may be very dependent on blood pressure. The patient's clinical condition and neurological status should determine treatment rather than an arbitrary level of blood pressure. Current recommendations are that emergency administration of antihypertensive agents should be withheld unless the systolic pressure is >220 mmHg (29 kPa) or the diastolic pressure is >120 mmHg (16 kPa). Aggressive lowering of blood pressure is not without risk and may result in progression of ischaemic stroke, so reduction should be monitored closely.[10] It would seem reasonable on physiological grounds to avoid drugs that cause cerebral vasodilatation in that they may aggravate cerebral oedema, although there is no hard evidence for this. Animal experiments suggested that haemodilution could improve blood flow by reducing whole-blood viscosity but a multicentre study failed to identify any clinical benefit and euvolaemia remains the ideal end-point.[11] Cardiac output should be maintained and any underlying cardiac

pathology such as failure, infarction and atrial fibrillation treated appropriately.

METABOLIC SUPPORT

Both hypo- and hyperglycaemia have been shown to worsen prognosis after acute stroke, therefore blood sugar levels should be maintained in the normal range.[12] In the long term, nutritional support must not be neglected and early enteral feeding instituted by nasogastric intubation. In the longer term, particularly where bulbar function is reduced, percutaneous endoscopic gastrostomy is necessary.

ANTICOAGULATION

In theory, the use of anticoagulation reduces the propagation of thrombus and should prevent further embolism. In practice, the reduction in risk of further thromboembolic stroke is offset by a similar number of patients dying from cerebral or systemic haemorrhage as a result of anticoagulation.[13,14] Anticoagulation can only be recommended in individuals where there is a high risk of recurrence, such as in those patients with prosthetic heart valves, atrial fibrillation with thrombus or those with thrombophilic disorders. A CT scan must be obtained prior to commencing therapy to exclude haemorrhage, and careful monitoring used. In patients with large infarcts there is always the risk of haemorrhage (haemorrhagic conversion) into the infarct and early heparinisation is best avoided.

THROMBOLYSIS

Thrombolysis with intravenous recombinant tissue plasminogen activator (rtPA alteplase) is now an established treatment for acute ischaemic stroke.[15] There are specific inclusion and exclusion criteria. Inclusion criteria are a diagnosis of ischaemic stroke causing measurable neurological deficit, age over 18 and less than 80 with an onset of symptoms to treatment time of less than 3 hours. Patients should be excluded if there is a history of head trauma or stroke (ischaemic or haemorrhagic) in the previous 3 months, evidence of subarachnoid or intracranial haemorrhage, arterial puncture in a non-compressible site in the past 7 days, any active bleeding or bleeding diathesis including platelet count less than 100 000/mm^3, heparin within 48 hours, current anticoagulant therapy, hypoglycaemia or multilobar infarction (more than one-third of a cerebral hemisphere) on CT scan. Relative contraindications include minor or rapidly improving stroke symptoms, seizure at time of stroke with residual post-ictal signs, major trauma in the past 14 days, GI or urinary tract bleeding in the past 21 days or myocardial infarction within the past 3 months.

There is some evidence for improved clinical outcome after rtPA use between 3 and 4.5 hours after symptom onset, although the degree of clinical benefit is less.[16] Patients must be in an environment where they can be monitored for potential complications, the most serious of which is intracranial haemorrhage. This risk is reduced where there is strict adherence to the inclusion and exclusion criteria and the appropriate dose used.

ENDOVASCULAR THERAPY

Selective catheterisation of the occluded cerebral arteries is possible and there have been some reports of direct intra-arterial infusion of thrombolytic drugs such as urokinase for middle cerebral artery strokes.[17] Mechanical disruption or displacement of the thrombus causing acute ischaemic stroke has been reported using several kinds of neuroembolectomy catheters placed on selective angiography allowing for fragmentation and suction of the clot.[18] Intravascular placement of self-expanding stents is also under investigation.[19] All of these methods are available only in specialist neuroradiology departments and have yet to be the subject of large-scale randomised trials.

CEREBRAL PROTECTION

Various agents such as free-radical scavengers, calcium antagonists, magnesium, amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) antagonists, glutamate antagonists and γ-aminobutyric acid antagonists have been used in attempts to limit the deleterious effects of the biochemical changes that occur intracellularly following ischaemia. No agent has been shown to be effective in placebo-controlled phase III trials.[20]

DECOMPRESSIVE CRANIECTOMY

Some patients with malignant middle cerebral artery infarction syndrome (MMCAS) may benefit from decompressive craniectomy, especially patients with large middle cerebral artery territory infarcts aged <60 years. Decompressive craniectomy must be done within 48 hours of symptom onset. The NNT for survival is 2 and for severe disability is 6. Untreated, MMCAS has a mortality of 80% and it is suggested craniectomy can reduce mortality to around 30%, but with residual neurological deficit. This procedure is limited to specialist centres. MMCAS development is predicted by MCA territory stroke of >50%, a perfusion deficit of >66% on CT, an infarct volume of >145 mL within 14 hours and >82 mL within 6 hours of onset. EEG and tissue cerebral tissue oxygenation have been used to predict cerebral oedema, ICP monitoring has not been proven to change outcome. Craniectomy has to be large enough to extend past the margins of the infarct. This seems to be well tolerated even after thrombolysis. There is no difference in outcome whether dominant or non-dominant hemispheres are involved. The patients who survive after craniectomy have moderate to severe disability and may have a high incidence of psychological complications. Whether this is acceptable to patients has not been studied.[21]

Other forms of surgical intervention proven to be effective in making more intracranial space and

reducing intracranial pressure are drainage of secondary hydrocephalus by extraventricular drain (EVD) insertion or evacuation of haemorrhage into infarcted areas, resulting in new compressive symptoms. This is especially useful in the posterior fossa where the room for expansion of mass lesions is limited by its anatomy.

COMPLICATIONS

Local complications include cerebral oedema, haemorrhage into infarcted areas or secondary hydrocephalus. General complications include bronchopneumonia, aspiration pneumonia, deep-vein thrombosis, urinary tract infections, pressure sores, contractures and depression. Stroke patients who are ventilated seem particularly susceptible to ventilator-acquired pneumonia.[22] A team approach of specialist nursing, physiotherapists, occupational and speech and language therapists is best able to avoid these complications.

SPONTANEOUS INTRACRANIAL HAEMORRHAGE

Spontaneous intracranial haemorrhage (ICH) producing stroke may occur from either intracerebral haemorrhage (10%) or SAH (5%).

INTRACEREBRAL HAEMORRHAGE

The incidence of intracerebral haemorrhage is about 9/100 000 of the population, mostly in the age range of 40–70 years, with an equal incidence in males and females.

AETIOLOGY AND PATHOLOGY

The commonest cause is the effect of chronic systemic hypertension. This results in degeneration of the walls of vessels or microaneurysms, by the process of lipohyalinosis, and these microaneurysms then suddenly rupture. This may also occur in malignant tumour neovasculature, vasculitis, mycotic aneurysms, amyloidosis, sarcoidosis, malignant hypertension, primary haemorrhagic disorders and over-anticoagulation.

Occasionally, cerebral aneurysms or AVMs may cause intracerebral haemorrhage without SAH. Where intracerebral haemorrhage occurs in young patients the most likely cause is an underlying vascular abnormality. In some areas this is also associated with the abuse of drugs with sympathomimetic activity such as cocaine. The rupture of microaneurysms tends to occur at the bifurcation of small perforating arteries. Common sites of haemorrhage are the putamen (55%), cerebral cortex (15%), thalamus (10%), pons (10%) and cerebellum (10%). Haemorrhage is usually due to rupture of a single vessel, and the size of the haemorrhage is influenced by the anatomical resistance of the site into which it occurs. The effect of the haemorrhage is determined by the area of brain tissue that it destroys. Cortical haemorrhages tend to be larger than pontine bleeds, but the latter are much more destructive owing to the anatomical density of neural tracts and nuclei.

CLINICAL PRESENTATION

Usually, there are no prodromal symptoms and a sudden onset of focal neurology or depressed level of consciousness occurs. Headache and neck stiffness will occur in conscious patients if there is subarachnoid extension by haemorrhage into the ventricles. Where intraventricular extension occurs there may be a progressive fall in GCS as secondary hydrocephalus occurs, and this may be accompanied by ocular palsies, resulting in 'sunset eyes'. Early deterioration is common in the first few hours after haemorrhagic stroke and more than 20% of patients will drop their GCS by two or more points between initial onset of symptoms and arrival in the emergency department.[23] As with ischaemic stroke, focal neurology is determined by which area of the brain is involved. The only way to differentiate absolutely between ischaemic, intracerebral or SAH is by appropriate imaging. The symptoms relate to tissue destruction, compression and raised intracranial pressure, which if progressive will result in brainstem ischaemia and death.

INVESTIGATIONS

The general investigations are essentially those listed previously for ischaemic stroke, since it is difficult to distinguish between the two in the early stages. Patients undergoing treatment with oral anticoagulants, particularly warfarin in atrial fibrillation, mean that anticoagulant-associated ICH is increasing in frequency and a full coagulation screen is essential.[24] CT and/or MRI should be performed at the earliest opportunity. The early deterioration seen in ICH relates to active bleeding and repeat imaging after 3 hours of symptom onset often shows significant enlargement of the initial haematoma. CT angiography/MR angiography or venography is very important to determine the cause of the haemorrhage such as arteriovenous malformations (AVM), aneurysm or tumour neovasculature (**Figs 51.2** and **51.3**). Lumbar puncture may be performed to exclude infection if mycotic aneurysm is suspected, but only after CT has excluded raised intracranial pressure or non-communicating hydrocephalus.

MANAGEMENT

The general management principles are identical to those for ischaemic stroke. There is, of course, no place for anticoagulation or thrombolysis, and reversal of any coagulation defect either primary or secondary to therapeutic anticoagulation must be undertaken as a matter of urgency. A full coagulation screen must be performed and the administration of vitamin K, fresh

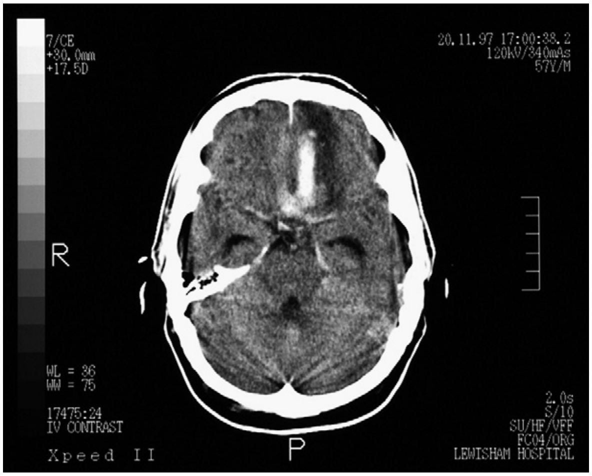

Figure 51.2 Left frontal intraparenchymal bleed with local oedema.

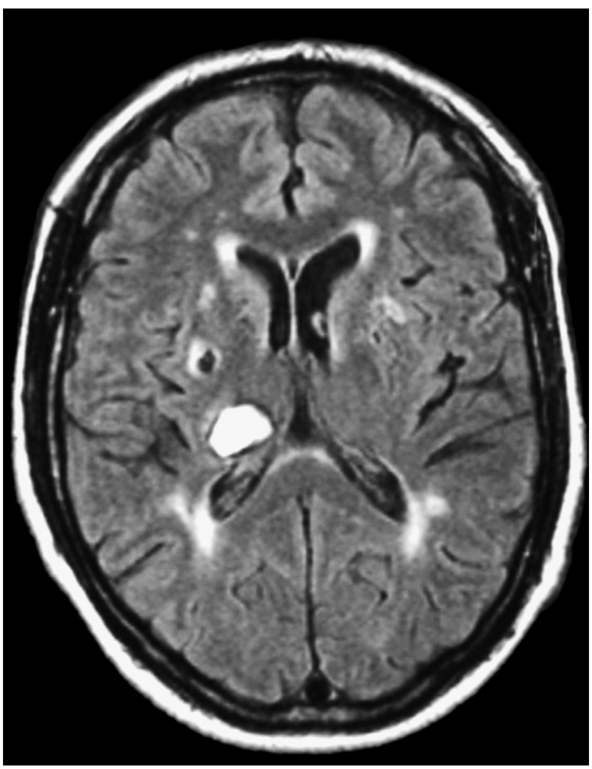

Figure 51.3 Magnetic resonance imaging: thalamic bleed.

frozen plasma, cryoprecipitate, etc., directed by the results. Where emergency decompressive surgery is indicated, warfarin-induced coagulopathy should be corrected using prothrombin complex concentrate (Beriplex or Octaplex). Intraventricular extension occurs in around 45% of cases and the insertion of an extraventricular drain (EVD) may increase conscious level, particularly in the presence of secondary hydrocephalus. The EVD level should be set such that the cerebrospinal fluid (CSF) drains at around 10 mmHg (1.33 kPa). The normal production of CSF should produce an hourly output and a sudden fall in output to zero should alert staff to the possibility that the drain has blocked. This is particularly likely if the CSF is heavily blood-stained. The meniscus of the CSF within the drain tubing should be examined for transmitted vascular pulsation or the level of the drain temporally lowered by a few centimetres to see if drainage occurs. If the drain is blocked, secondary hydrocephalus will recur. Because of the risk of introducing infection and causing a ventriculitis, the drain must be unblocked in a sterile manner by the neurosurgeons. Blood in the CSF acts as a pyrogen, but the patient's high temperature should never be ascribed to this alone and regular blood cultures and CSF samples are required as part of sepsis surveillance. Operative decompression of the haematoma should be undertaken only in neurosurgical centres and safe transfer must be assured if this is considered. The administration of mannitol prior to transfer should be discussed with the neurosurgical unit. There is some evidence that patients with supratentorial intracerebral haemorrhage less than 1 cm from the cortical surface benefitted from surgery within 96 hours, although this finding did not reach statistical significance.[25] Patients presenting with a GCS of less than 8/15 had an almost universally poor outcome. Not all intracerebral haematomata are amenable to surgery, and the CT scans should be reviewed by the neurosurgical unit, preferably prior to transfer by digital image link. In patients with a cerebellar ICH larger than 3 cm in diameter, or those with brainstem compression or secondary hydrocephalus, surgical decompression gives better results than those managed medically and despite the lack of randomised trials the current recommendation is to remove the clot surgically.[26]

The management of hypertension following spontaneous intracerebral haemorrhage may be difficult as too high a blood pressure (BP) may provoke further bleeding, whereas too low a BP may result in ischaemia. Current recommendations of the American Heart Association/American Stroke Association are to lower BP if the systolic BP is >200 mmHg (26.6 kPa) (MAP > 150) with monitoring every 5 minutes. If the SBP is >180 mmHg (23.9 kPa) or MAP is >130 mmHg (17.3 kPa) and a high ICP is suspected then ICP and CCP should be measured while the BP is reduced keeping CPP above 60 mmHg (8 kPa). If SBP is >180 mmHg (23.9 kPa) or MAP is >130 mmHg (17.3 kPa) but no evidence of increased ICP then the MAP should be reduced to 110 mmHg or a target BP of 160/90.[26] These guidelines are not evidence based. The INTERACT2 trial on acute targeted blood pressure control after spontaneous intracerebral haemorrhage has shown that a systolic target of 140 mmHg was safe. It did not result in a significant reduction in death or major disability although there was a trend towards improved functional

outcome.[44] The adoption of these guidelines may have significant resource indications regarding access to ICU beds to provide the required levels of monitoring. There is no place for steroids, and hyperventilation to Pa_{CO_2} of 30 mmHg (4 kPa) or less to control raised intracranial pressure will have detrimental effects on cerebral blood flow in other areas of the brain.

SUBARACHNOID HAEMORRHAGE

SAH refers to bleeding that occurs principally into the subarachnoid space and not into the brain parenchyma. The incidence of SAH is around 6/100 000; the apparent decrease, compared with earlier studies, is due to more frequent use of CT scanning, which allows exclusion of other types of haemorrhage. Risk factors are the same as for stroke, but SAH patients are usually younger, peaking in the sixth decade, with a female-to-male ratio of 1.24:1. People of Afro-Caribbean ancestry have twice the risk for SAH as whites. Between 5 and 20% of patients with SAH have a positive family history, with first-degree relatives having a three- to sevenfold risk, whereas second-degree relatives have the same degree of risk as the general population. Specific inheritable disorders are rare and account for only a minority of all patients with SAH.[23] The only modifiable risk factors for SAH are smoking, heavy drinking, the use of sympathomimetics (e.g. cocaine) and hypertension, which increase the risk odds ratio by 2 or 3. Overall mortality is 50%, of which 15% die before reaching hospital, with up to 30% of survivors having residual deficit producing dependency. High-volume centres (>60 cases per year) have shown a much-improved outcome over that of low-volume centres (<20 cases per year).[27]

AETIOLOGY AND PATHOLOGY

The majority of cases of SAH are caused by ruptured saccular (berry) aneurysms (85%), the remainder being caused by non-aneurysmal perimesencephalic haemorrhage (10%) and rarer causes such as arterial dissection, cerebral or dural AVMs, mycotic aneurysm, pituitary apoplexy, vascular lesions at the top of the spinal cord and cocaine abuse. Saccular aneurysms are not congenital, almost never occur in neonates and young children and develop during later life. It is not known why some adults develop aneurysms at arterial bifurcations in the circle of Willis and some do not. It was thought that there was a congenital weakness in the tunica media, but gaps in the arterial muscle wall are equally as common in patients with or without aneurysms and, once the aneurysm is formed, the weakness is found in the wall of the sac and not at its neck.[28] The association with smoking, hypertension and heavy drinking would suggest that degenerative processes are involved. Sudden hypertension plays a role in causing rupture, as shown by SAH in patients taking crack cocaine or, rarely, high doses of decongestants such as pseudoephedrine.

CLINICAL PRESENTATION

Classically, there is a 'thunderclap' headache developing in seconds, with half of patients describing its onset as instantaneous. This is followed by a period of depressed consciousness for less than an hour in 50% of patients, with focal neurology in about 30% of patients. About a fifth of patients recall similar headaches and these may have been due to sentinel bleeds; this increases the chances of early rebleed 10-fold. The degree of depression of consciousness depends upon the site and extent of the haemorrhage. Meningism – neck stiffness, photophobia, vomiting and a positive Kernig's sign – is common in those patients with higher GCS. A high index of suspicion is needed for patients presenting with the classical headache; a non-contrast CT is recommended and, if negative, a lumbar puncture should be done. If that is also negative, consider computed tomographic angiography (CTA).

The clinical severity of SAH is often described by a grade, the most widely used being that described by the World Federation of Neurological Surgeons (WFNS),[29] which is summarised in **Table 51.1**. This grading, together with the extent of the haemorrhage and the age of the patient, gives some indication of the prognosis, in that the worse the grade the bigger is the bleed, and the older the patient the less likely a good prognosis. Other poor prognostic signs are pre-existing severe medical illness, clinically symptomatic vasospasm, delayed multiple cerebral infarction, hyperglycaemia, fever, anaemia and medical complications such as

Table 51.1 Clinical neurological classification of subarachnoid haemorrhage

GRADE	SIGNS
I	Conscious patient with or without meningism
II	Drowsy patient with no significant neurological deficit
III	Drowsy patient with neurological deficit – probably intracerebral clot
IV	Deteriorating patient with major neurological deficit (because of large intracerebral clot)
V	Moribund patient with extensor rigidity and failing vital centres

WFNS GRADE	*GCS*	*MOTOR DEFICIT*
I	15	Absent
II	14–13	Absent
III	14–13	Present
IV	12–7	Present or absent
V	3–6	Present or absent

WFNS = World Federation of Neurological Surgeons; GCS = Glasgow Coma Score.

pneumonia and sepsis. Anatomical risk factors may increase periprocedural risk of complications. On the other hand better outcomes seem to be associated with treatment in a high-volume centre.

In a recently published study on the natural history of cerebral aneurysms, the annual rupture rate was 0.95%. Risk factors that made it more likely to rupture were the location, MCA more likely than posterior communicating (PCOM) or anterior communicating (ACOM), size (the larger the more likely to rupture) and if the aneurysm has an irregular shape.[30]

COMPLICATIONS

The clinical status of the patient may be complicated by factors other than the physical effect of initial bleed, and factors such as acute hydrocephalus, early rebleeding, cerebral vasospasm, parenchymal haematoma, seizures and medical complications must be considered.

REBLEEDING

This may occur within the first few hours after admission and 15% of patients may deteriorate from their admission status. They may require urgent intubation and resuscitation, but not all rebleeds are unsurvivable and such deterioration should be treated. The chance of rebleeding is dependent on the site of the aneurysm, presence of clot, degree of vasospasm, age and sex of the patient. Although most studies quote an incidence for rebleeding of 4% in the first 24 hours, more recent studies suggest an incidence of 9–17% with most cases occurring within 6 hours. A few small studies have shown that antifibrinolytics such as tranexamic acid can be used, early, short term (<72 hours) in patients who do not have a pre-existing high risk for thrombotic events, for the prevention of rebleeding while awaiting securing of the aneurysm. It is an off-licence use of antifibrinolytics.[31]

ACUTE HYDROCEPHALUS

This may occur within the first 24 hours post ictus and is often characterised by a drop in the GCS, sluggish pupillary responses and bilateral downward deviation of the eyes ('sunset eyes'). If these signs occur, CT scan should be repeated and, if hydrocephalus is confirmed or there is a large amount of intraventricular blood, then a ventricular drain may be inserted. This is not without risk as it may provoke more bleeding and introduce infection. Only observational studies exist and these are contradictory so no firm recommendation can be made (**Fig. 51.4**).

Figure 51.4 Spontaneous subarachnoid haemorrhage and secondary hydrocephalus.

DELAYED CEREBRAL ISCHAEMIA (DCI)

Vasospasm is the term used to describe narrowing of the cerebral blood vessels in response to SAH seen on angiography. It occurs in up to 70% of patients, but not all of these patients will have symptoms. Delayed cerebral ischaemia refers to the onset of focal neurological deficit, drop in GCS by 2 or more points, and/or cerebral infarction that occurs typically 4–12 days post SAH unrelated to aneurysm treatment or other causes of neurological deficit such as hydrocephalus, cerebral oedema or metabolic disorder.[32] Use of transcranial Doppler (TCD) to estimate middle cerebral artery blood velocity has shown that a velocity of more than 120 cm/s correlates with angiographic evidence of vasospasm. This technology allows diagnosis in the ICU and provides a means of monitoring the success of treatment to reduce DCI, which is undertaken to reduce the severity of delayed neurological deficit secondary to vasospasm. The problem is that not all patients who have angiographic vasospasm or high Doppler velocities have symptoms. If there is evidence of a depressed level of consciousness in the absence of rebleeding, hydrocephalus or metabolic disturbances, but there is evidence of DCI clinically, on TCD or angiogram, then it would seem appropriate to initiate treatment. If vasospasm occurs at the time of angiography or coiling, then intravascular vasodilators such as papaverine or nimodipine have been used. CTA is the imaging modality of choice unless intracerebral therapy is planned, then DSA is recommended as first-line imaging.

PARENCHYMAL HAEMATOMA

This may occur in up to 30% of SAH following aneurysm rupture and has a much worse prognosis than SAH alone. If there is mass effect with compressive symptoms then evacuation of haematoma and simultaneous clipping of the aneurysm may improve outcome.

MEDICAL COMPLICATIONS

During the placebo-controlled study of nicardipine in WFNS grade I and II SAH patients, there was a 40% incidence of at least one life-threatening medical complication in the placebo group.[33] The mortality due to medical complications was almost the same as that due to the combined effects of the initial bleed, rebleeds and

Table 51.2 Types of medical complication seen in patients with subarachnoid haemorrhage

MEDICAL COMPLICATION	INCIDENCE (%)
Arrhythmias	35
Liver dysfunction	24
Neurogenic pulmonary oedema	23
Pneumonia	22
ARDS and atelectasis	20
Renal dysfunction	5

ARDS = acute respiratory distress syndrome.

delayed cerebral ischaemia. The types of medical complication seen are shown in **Table 51.2**.

INVESTIGATIONS

The general investigations for stroke should be performed and early CT imaging is mandatory. Blood appears characteristically hyperdense on CT and the pattern of haemorrhage may enable localisation of the arterial territory involved. Very rarely, a false-positive diagnosis may be made if there is severe generalised oedema resulting in venous congestion in the subarachnoid space. Small amounts of blood may not be detected and the incidence of false-negative reports is around 2%.[34] It may be difficult to distinguish between post-traumatic SAH and primary aneurysmal SAH, which precipitates a fall in the level of consciousness that provokes an accident or fall. MR scanning is particularly effective for localising the bleed after 48 hours when extravasated blood is denatured, and provides a good signal on MRI.[34]

Lumbar puncture is still necessary in those patients where the suspicion of SAH is high despite a negative CT, or there is a need to exclude infection. There must be no raised intracranial pressure and at least 6 hours should have passed to give time for the blood in the CSF to lyse, enabling xanthochromia to develop.

Angiography via arterial catheterisation is still the most commonly used investigation for localising the aneurysm or other vascular abnormality prior to surgery. It is generally performed on patients who remain, or become, conscious after SAH. It is not without risk and aneurysms may rupture during the procedure and a meta-analysis has shown a complication rate of 1.8%. Other methods under investigation include CT angiography and MR angiography. Digital subtraction angiography (DSA) is the diagnostic tool of choice in cases where CTA is still inconclusive.[35]

Intracranial pressure monitoring is of limited use in SAH patients except in those where hydrocephalus or parenchymal haematoma is present and early detection of pressure increases may be the trigger for drainage or decompressive surgery.

Transcranial Doppler studies may be useful in detecting vasospasm or those patients in whom autoregulation is impaired.[36] The technique is dependent on there being a 'window' of thin temporal bone allowing insonation of the Doppler signal along the middle cerebral artery. It is very user-dependent and 15% of patients do not have an adequate bone window.

MANAGEMENT

The initial management of SAH is influenced by the grading, medical co-morbidity or complications, and the timing or need for surgery. Patients with decreased GCS may need early intubation and ventilation, simply for airway protection, whereas those with less severe symptoms require regular neurological observation, analgesia for headache and bed rest prior to investigation and surgery. Other management options are: stress ulcer prophylaxis, deep-vein thrombosis prophylaxis using compression stockings or boots, and seizure control with phenytoin or barbiturates. If the patient is sedated and ventilated, the use of an analysing cerebral function monitor should be considered to detect subclinical seizure activity.

Hyponatraemia is a common finding and adequate fluid therapy with normal saline is required with electrolyte levels maintained in the normal range. Occasionally, as in other types of brain injury, excessive natriuresis occurs and may result in hyponatraemic dehydration – cerebral salt-wasting syndrome (CSWS).[37] Its aetiology is not known, but some suggest increased levels of atrial natriuretic peptide. It usually occurs within the first week after insult and resolves spontaneously in 2–4 weeks. Failure to distinguish CSWS from the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) could lead to inappropriate treatment by fluid restriction, which would have adverse effects on cerebral perfusion. Urine sodium concentrations are usually elevated in both SIADH and CSWS (>40 mmol/L) but urinary sodium excretion, urine sodium concentration [Na mmol/L]×urine volume [L/24 hours] is high in CSWS and normal in SIADH. If CSWS does not respond to fluid replacement with saline or is not self-limiting then fludrocortisone therapy may be useful.

BLOOD PRESSURE CONTROL

Elevation of blood pressure is commonly seen after SAH and there are no precise data on what constitutes an unacceptably high pressure that is likely to cause rebleeding. Equally, there are no precise data on a minimum level of pressure below which infarction is likely to occur, since this will depend on the patient's normal pressure, degree of cerebral oedema and the presence or absence of intact autoregulation. One observational study has demonstrated reduced rebleeding, but higher rates of infarction, in newly treated

compared with untreated post-SAH hypertensive patients. Although there are no precise data on specific blood pressure controls, the AHA guidelines recommend that systolic blood pressure is kept <160 mmHg (21.3 kPa) or mean arterial pressure of <110 mmHg (14.6 kPa) in a person with an unsecured aneurysmal SAH.[38] Beta-adrenergic blockers or calcium antagonists are the most widely used agents, since drugs producing cerebral vasodilation may increase intracranial pressure. The choice is less important than the titratability of the drug, as the balance between increase of rebleed and cerebral perfusion needs to be maintained. If nimodipine causes severe hypotension, timing and dose need to be changed too (i.e. 30 mg 2-hourly instead of 60 mg 4-hourly). If nimodipine still remains a problem, consider omitting doses until more cardiovascularly stable.

DELAYED CEREBRAL ISCHAEMIA (DCI)

Angiographic demonstration of vasospasm may be seen in about 70% of SAH patients, but only about 30% develop cerebral symptoms related to vasospasm, hence the change of nomenclature. Transcranial Doppler-derived flow velocities in the middle cerebral arteries of more than 120 cm/s are accurate in predicting ischaemia. Symptoms tend to occur between 4 and 14 days post bleed, which is the period when cerebral blood flow is decreased after SAH.

PREVENTION

One method of pre-empting vasospasm is the prescription of oral nimodipine at 60 mg given 4-hourly for 21 days, which has been shown to achieve a reduction in the risk of ischaemic stroke of 34%.[39] Intravenous nimodipine should be used in the patients who are not absorbing, but it must be titrated against blood pressure to avoid hypotension. Other calcium antagonists, notably nicardipine and the experimental drug AT877, reduce vasospasm but do not improve outcome.

There have been some studies looking at statins to prevent DCI. These have been small trials but have shown promising results. A large randomised control trial (STASH) is under way to give us definitive answers on statins. Statins should at least be considered in the prevention of DCI and definitely continued if they were prescribed pre-event. [38]

Routine hypermagnesaemia for the prevention of DCI is not recommended, but hypomagnesaemia should be prevented. The 2012 MASH 2 trial showed no improvement in clinical outcome following routine administration of intravenous magnesium.

TREATMENT

Low cerebral blood flow is known to worsen outcome and this resulted in the development of prophylactic hypertensive hypervolaemic haemodilution – so-called triple-H therapy.[40] As originally described, the therapy involved the use of fluid loading to achieve haemodilution and vasopressor therapy to increase cerebral blood flow, and was combined with surgery within 24 hours if possible. The therapy was continued for 21 days and all patients remained neurologically stable or improved as a result, apparently, of the absence of vasospasm. Very few centres use the strict protocol as originally described, but fluid loading rather than fluid restriction is the norm and inotropes or vasopressors are used subsequently if neurological function decreases. Despite its widespread use, there remains no prospective randomised trial that demonstrates its utility. The focus now is on normovolaemia and, if indicated and blood pressure not already raised, hypertension is induced with vasopressors. This needs to be done in a stepwise fashion with assessment of neurological function at each step.[38] Cerebral angioplasty or direct intracerebral vasodilators should be considered if induced hypertension is not reversing the DCI symptoms.[38] Where symptoms develop it is important to exclude other causes such as rebleeding, hydrocephalus or metabolic disorder. Poor-grade SAH patients who are sedated or have low GCS are clinically difficult to assess; multimodal monitoring is recommended to look for deterioration.[38]

SEIZURES

Seizure occurs in up to 26% of SAH sufferers. The evidence for prophylactic use of anticonvulsants is poor and not recommended. Some prognostic indicators for the development of seizures have been identified: increased intracerebral blood, poor-grade SAH, rebleeding infarction and MCA aneurysm. Patients should be observed for seizure activity and treated appropriately. A patient with poor-grade SAH who is not improving or is deteriorating neurologically, from an unknown cause, should have continuous EEG monitoring.[38]

SURGERY

Clipping of the aneurysm is the surgical treatment of choice, with wrapping, proximal ligation or bypass grafting being used if the aneurysm is inaccessible to Yasargil clipping. The timing of surgery remains debatable. Early surgery, within 3 days of the bleed, has the advantage of fewer deaths occurring from rebleeding but is technically difficult owing to the friability of associated tissues. Delayed surgery, around 10–12 days post bleed, gives better operating conditions but allows some patients to suffer a rebleed. Recommendations by the AHA are to secure the aneurysm as early as is possible. Large intracerebral haematomas associated with the SAH and middle cerebral artery aneurysms should be strongly considered for surgery. There is no good level one evidence for the use of induced hypertension or hypothermia during clipping, but in certain patients it could be considered. What is clear is that hypotension and hyperglycaemia should be avoided.[38]

ENDOVASCULAR COILING

The development of detachable microcoils made of platinum by Guglielmi in 1992 has resulted in endovascular embolisation of aneurysms or AVMs by interventional radiology.[41] A microcatheter is passed from the femoral artery to the cerebral aneurysm and the coils positioned sequentially in the lumen of saccular aneurysms to occlude it. Rupture of the aneurysm or adjacent vessel occlusion, causing ischaemia, is the most frequent complication. The International Subarachnoid Aneurysm Trial (ISAT) of neurosurgical clipping versus endovascular coiling in 2143 patients with ruptured intracranial aneurysms – a randomised comparison of effects on survival, dependency, seizures, rebleeding, subgroups and aneurysm occlusion – has come down in favour of coiling rather than open surgical technique at 1-year follow-up. In patients with ruptured intracranial aneurysms suitable for both treatments, endovascular coiling is more likely to result in independent survival at 1 year than neurosurgical clipping; the survival benefit continues for at least 7 years. The risk of late rebleeding is low, but is more common after endovascular coiling than after neurosurgical clipping.[42] Additional complications of coiling include rupture during catheter placement in the aneurysm, coil embolisation and vasospasm. Not all aneurysms, particularly those with wide necks, multiple filling vessels or giant aneurysms, are suitable for coiling. Aneurysms that are amenable to either surgery or coiling should be coiled; if patients are elderly (>70 years) or have poor-grade SAH then coiling is preferred. Stenting of acute SAH carries a worse prognosis.[38]

NEUROPROTECTIVE THERAPY

There has been a great deal of research on the cellular and biochemical responses to brain injury and several drugs have been investigated to try to reduce mortality in SAH. The 21-amino steroid tirilazad, nicaraven and ebselen, all free-radical scavengers, have been the most widely investigated. None has been shown to improve outcome consistently in all types of patient with SAH.

THERAPY OF MEDICAL COMPLICATIONS

This is obviously specific to the type of complication. Pneumonia may require continuous positive-airways pressure or ventilatory support together with directed antimicrobial therapy, acute respiratory distress syndrome requires lung-protective/recruitment ventilatory strategies, and renal failure necessitates an appropriate means of renal replacement therapy. Arrhythmias require correction of trigger factors such as hypovolaemia and electrolyte or acid–base disturbances prior to the appropriate antiarrhythmic drug or DC cardioversion. Cardiac function should be evaluated in patients with cardiovascular deterioration, by means of serial enzymes and echocardiography. Cardiac output monitoring should be considered. Neurogenic pulmonary oedema may be associated with severe cardiogenic shock, which may require inotropic support or even temporary intra-aortic balloon counterpulsation. The cardiogenic shock is reversible and patients can make a good recovery despite the need for aggressive support.[43]

Hyper- and hyponatraemia are frequently seen, with hyponatraemia occurring in up to 30% of cases and implicated in the development of DCI. The aim is for normovolaemia; if it cannot be achieved because of a persistent negative fluid balance as a result of cerebral salt-wasting syndrome, then fludrocortisone should be considered. Hyponatraemia should be corrected by no more than 0.5 mmol/L per hour with a maximum of 8 mmol/L per day (if it is chronic, i.e. of more than 48 hours' duration) during which 4-hourly sodium levels should be taken. This may be achieved by using intravenous fluid that has more sodium than the serum concentration of the patient. In patients who are resistant to vasopressors, hypothalamic dysfunction should be considered and hydrocortisone should be administered, but no more than 300 mg per day.

Blood glucose should be kept at 4.4–11.1 mmol/L (80–200 mg/dL), as higher and lower levels of blood glucose has been shown to be detrimental to outcome.

Fever should be controlled by antipyretics as first line, especially when DCI is suspected. Cooling devices should be considered if first-line antipyretics have failed, but care should be taken to monitor for pressure ulcers and venous thrombotic events. Shivering needs to be addressed, as this will be counterproductive to therapy by increasing oxygen consumption.

Deep-vein thrombosis prophylaxis should be instituted as soon as possible in the form of graduated compression devices; heparin (unfractionated or low-molecular weight) should be started 24 hours after securing of the aneurysm.

Anaemia should be minimised by limiting the amount of blood taken for blood test. A transfusion trigger of 8–10 g/dL has been recommended.

Cerebral protection

Victoria Heaviside and Michelle Hayes

The cerebral circulation is arguably the most important and most vulnerable in the body. Circulatory impairment or arrest for only a few minutes can cause neuronal death. Cerebral protection is the application of therapeutic interventions following a primary brain injury, in the hope of preventing secondary injury and improving neurological outcome. It has been incorporated into the prophylaxis, treatment and management of brain injury irrespective of aetiology. A complete review is beyond the scope of this chapter, but an understanding of the current approaches to cerebral protection is certainly helpful in the management of cerebral insults.

NORMAL BRAIN PHYSIOLOGY

The brain has high energy requirements, utilising approximately 3–5 mL O_2/min per 100 g tissue (45–75 mL O_2/min per 1500 g brain) and 5 mg glucose/min per 100 g tissue (75 mg glucose/min per 1500 g brain). It has little ability to store precursors of metabolism and thus depends on a constant supply of nutrients from the blood.

With a cerebral blood flow (CBF) of 50 mL/min per 100 g tissue (750 mL/min per 1500 g brain) and a normal oxygen content of 20 mL O_2/100 mL blood, the brain receives approximately 150 mL O_2/min per 1500 g brain, or 2–3 times the amount needed for normal brain activity.

At the same CBF of 50 mL/min per 100 g tissue and a blood glucose concentration of 5.5 mmol/l (100 mg/100 mL blood), there is 50 mg/min per 100 g tissue (750 mg/min per 1500 g brain) delivery of glucose. Glucose extraction by the brain, at 5 mg/min per 100 g brain tissue, is a tenth of that delivered; minimal compared with oxygen.

Although cerebral injury has many aetiologies, the mechanisms of injury are thought to be few. The most common is lack of the essential nutrients, oxygen and glucose, either separately with preserved blood flow (i.e. hypoxia or hypoglycaemia), or together, because of reduced or absent perfusion (i.e. ischaemia or infarction). A reduction in these energy precursors is a major contributor in the mechanism of brain injury.

NATURAL PROTECTIVE MECHANISMS

The importance of the brain is highlighted by the presence of integral protective mechanisms that aim to prevent cerebral ischaemia.

COLLATERAL BLOOD SUPPLY

An elaborate vascular architecture is designed to ensure adequate CBF. The anterior cerebral circulation is provided by bilateral internal carotid arteries as they each divide into anterior and middle cerebral arteries. They provide approximately 70% of the cerebral circulation and supply the anterior cerebrum (frontal, parietal and temporal lobes) and anterior diencephalon (basal ganglia and hypothalamus). The remaining 30% of the cerebral circulation is provided posteriorly by the vertebrobasilar system, which runs the length of the posterior fossa, supplying the brainstem, cerebellum, posterior portion of the cerebrum (occipital lobes) and diencephalon (thalamus). These two circulations are joined by communicating arteries, ultimately forming the circle of Willis (**Fig. 52.1**). This joining of the anterior and posterior circulations at the base of the brain is the major component of cerebral vasculature in humans. Between these arterial distributions are watershed zones fed by leptomeningeal connections. In addition, persistent fetal arteries can infrequently provide collateral routes between the anterior and posterior arterial systems in the brain.

CEREBRAL BLOOD FLOW

CEREBRAL PERFUSION PRESSURE

The amount of blood delivered to the brain is highly regulated and is determined by several factors. CBF is determined in part by the perfusion pressure across the brain, called cerebral perfusion pressure (CPP). CPP is the difference between the arterial pressure in the feeding arteries as they enter the subarachnoid space and the pressure in the draining veins before they enter the major dural sinuses. These pressures are difficult to measure, thus CPP is derived from the difference between the systemic mean arterial pressure (MAP)

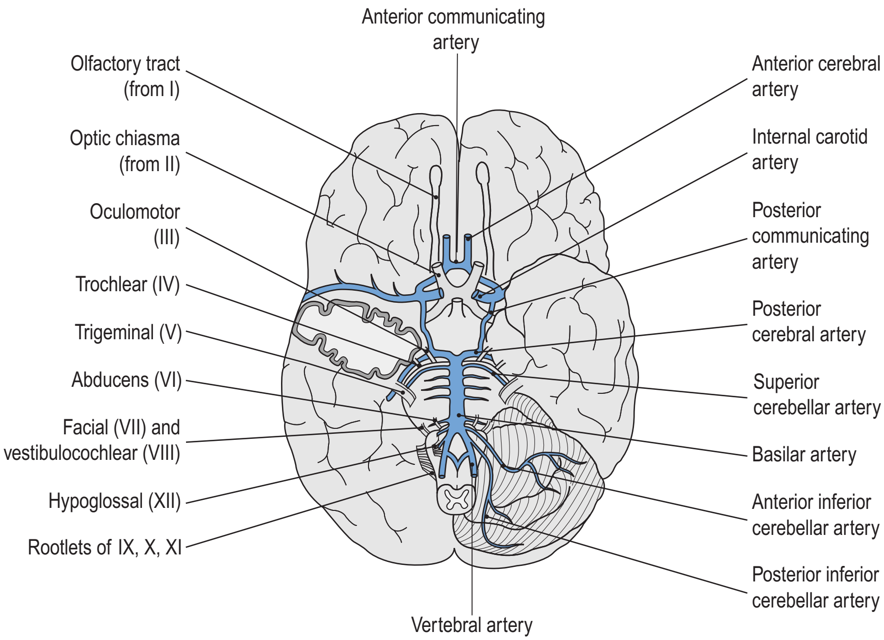

Figure 52.1 Circle of Willis.

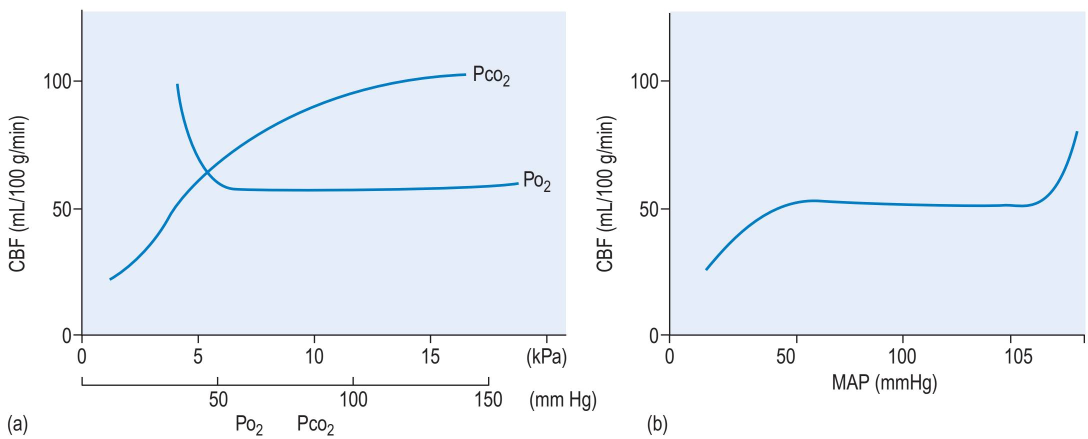

Figure 52.2 (a) The relationship between the partial pressure of oxygen (P_{O_2}) and carbon dioxide (P_{CO_2}) and cerebral blood flow (CBF). (b) The relationship between mean arterial pressure (MAP) and cerebral blood flow under normal circumstances, illustrating the range of autoregulation.

and the intracranial pressure (ICP) (an estimate of tissue pressure).

The cerebral vessels change diameter inversely with changing perfusion pressure. As CPP rises, the vessels constrict and as CPP falls the vessels dilate, such that blood flow is kept constant over a wide range of CPP (**Fig. 52.2a**). This 'autoregulated' pressure is thought to be controlled by local myogenic responses of the vessel wall to changes in intra-arterial pressure. At pressures above and below this range of 6.7–20 kPa (50–150 mmHg), cerebral perfusion becomes pressure-passive and increases or decreases in direct proportion to changes in CPP. The autoregulatory range varies with age, being shifted to the left in newborns and to the right in those with chronic hypertension. The latter is important to remember to avoid overtreating systolic blood pressure in such patients and thus incur the risk of cerebral ischaemia at the lower limits of autoregulation. Alternatively, cerebral perfusion above normal can be caused by acute hypertension overcoming the upper limits of autoregulation. This may lead to cerebral oedema secondary to increased hydrostatic pressures (hypertensive encephalopathy) and potentially lead to seizures or cerebral haemorrhage.

Pa_{O_2} AND Pa_{CO_2} EFFECTS

Oxygen and carbon dioxide manipulate CBF through an influence on the local metabolic milieu. The arterial content or partial pressure of oxygen in the normal or hyperoxic range causes very little change in CBF. This changes with the onset of hypoxaemia (Pa_{O_2} 60 mmHg or 8 kPa), where there is a prompt increase in CBF proportional to the decrease in blood oxygen content, in order to maintain oxygen delivery constant (Fig. 52.2b).

There is also a direct relationship between CBF and Pa_{CO_2}, such that CBF increases with increasing Pa_{CO_2} (Fig. 52.2b). This probably represents the need of the brain to maintain a homeostatic pH by removing metabolic breakdown products more efficiently through increased blood flow. Unlike the response to oxygen, the CBF response to changes in Pa_{CO_2} is dramatic in the physiological range, such that for every 0.13 kPa (1.0 mmHg) change in Pa_{CO_2} there is a 1–2 mL/min per 100 g tissue change in CBF. Therefore, an increase in Pa_{CO_2} to 10.6 kPa (80 mmHg) will increase CBF to approximately 100 mL/min per 100 g and a decrease in Pa_{CO_2} to 2.7 kPa (20 mmHg) will decrease CBF to 25 mL/min per 100 g. Thus:

- doubling Pa_{CO_2} doubles CBF
- halving Pa_{CO_2} halves CBF within this range.

Understanding this basic physiology will make treatment logical (see below), as increases in CBF often lead to increases in cerebral blood volume, which in turn can increase ICP, a common cause of cerebral ischaemia and a significant predictor in patient outcome.

CEREBRAL INJURY

Vascular insufficiency or disruption, trauma, tumour, infection, inflammation and metabolic and nutritional derangement can all cause damage. Whatever the cause, the mechanism of injury is usually hypoxic and/or ischaemic injury. Therefore, it is possible to have high flow but no oxygen or, alternatively, no flow but plenty of oxygen. At the cellular level the consequence is the same.

The protective mechanisms that are in place to increase CBF with the generous oversupply of nutrients under normal conditions, allow for sufficient blood flow, oxygen delivery and supply of nutrients in milder injurious cases. However, in situations of trauma and developing pathology such as cerebrovascular disease restricting perfusion, or intracranial masses causing oedema, alterations in blood flow, hypoxia and or ischaemic injury will occur. This in turn can disturb systemic circulatory homeostasis, cause hypotension and worsen the ischaemic injury further. Thus hypoxic and ischaemic injury may be considered synonymous, be there aetiological differences between them. A more important distinction to be made is that between global and focal hypoxic or ischaemic insults.

GLOBAL HYPOXIC/ISCHAEMIC INSULTS

These types of insult are caused by hypoxaemia and cardiovascular insufficiency or arrest, respectively. These are usually sudden, short and severe. If there is to be recovery, prompt return of oxygen delivery and spontaneous circulation are necessary. The recovery may be variable, depending on the severity and duration of the insult and the selective vulnerability of the cell types involved. Different mechanisms are responsible for reversible loss of cellular function and for irreversible cell death and there are also differences between the mechanisms that cause death of neurons, glia and endothelial cells. After 4–6 minutes of complete global ischaemia, there are signs of permanent histological damage in selective neuronal populations and the beginnings of neurological deficits in survivors. Outcome worsens significantly after 15 minutes of global ischaemia.[1]

FOCAL HYPOXIC/ISCHAEMIC INSULTS

These insults often occur suddenly but are usually of more prolonged duration. Only a subtotal of the brain is affected and the injury may be less severe if the surrounding brain is preserved by collateral blood supply.

The area of the focal ischaemia supplied by end-arteries will result in cell death unless reperfusion is established rapidly. The periphery of an infarcted area is the ischaemic penumbra. Here, CBF is greater than at the infarcted core, but less than in the normal tissue around it. Animal studies suggest that the time course for infarction and irreversible damage to brain from a focal hypoxic/ischaemic event is around 30–60 minutes. The focus of therapeutic intervention is the penumbral area, on the basis that if blood flow can be normalised in this region, or pharmacological agents can be delivered despite the reduced blood flow, there is a potential for recovery. Conversely, failure to maintain this area will result in a coalescing of the penumbra into the infarcted area, as the ischaemic stimulus continues.

It is likely that the ongoing ischaemic penumbral areas of a focal insult and transient whole-brain ischaemia (e.g. during early cardiac arrest, low-flow cardiopulmonary resuscitation (CPR) or elevated ICP states) are subject to similar pathophysiological processes. As pretreatment is usually impossible, prevention and treatment of the secondary insult is the focus in neuroprotection and tissue salvage strategies.

BRAIN ISCHAEMIC AND INFARCTION PROCESSES

Changes in normal physiology begin to occur when blood flow is reduced.

- At CBF below 50 mL/min per 100 g neurological function is impaired and there is slowing of the electroencephalogram (EEG).

- A CBF of 15–25 mL/min per 100 g results in loss of electrical activity.
- A CBF between 10 and 15 mL/min per 100 g can maintain adenosine triphosphate (ATP) levels sufficiently to support ionic pump function for a time, despite the lack of electrical activity and normal neurological function.
- At a CBF of 10 mL/min per 100 g membrane failure occurs, due to a critical loss of ATP, which causes ionic imbalance between the cell and the extracellular milieu. If prolonged or worsened, CBF at this level will lead to permanent neurological impairment as a result of cell death.

EFFECTS OF ISCHAEMIA

In the non-fasting state, glucose is metabolised to ATP via oxidative phosphorylation. ATP is needed for homeostasis and cellular activities such as mitochondrial expression, protein synthesis, ionic gradient maintenance, cell membrane stability and CO_2 elimination. Ischaemia results in reduced availability of oxygen and glucose to support aerobic production of ATP. Levels of ATP are depleted within 2–3 minutes of complete ischaemia (animal studies). There is little brain storage of either glucose or oxygen, and ATP production during ischaemia relies on anaerobic glycolysis for as long as stores last. This results in continued ATP use, but suboptimal production of ATP to fuel aerobic metabolism, so a lactic acidosis develops.

Loss of ATP causes failure of membrane ionic pump function, the beginnings of cytotoxic oedema and a cascade of events, which result in eventual cell death:

- potassium efflux with cell membrane depolarisation, ion channel opening and the release of excitatory amino acid (EAA) neurotransmitters (glutamate, aspartate and others)
- EAA damage by further depolarisation of neighbouring and distal unaffected cells
- sodium and chloride influx via kainate (K) and quisqualate (Q) receptors (with worsening intracellular oedema)
- sodium and calcium influx via *N*-methyl-D-aspartate (NMDA) receptors
- conversion of phosphorylases, uncoupling of oxidative phosphorylation, activation of proteases, degradation of cystosolic protein and stimulation of lipases. Lipases liberate arachidonic acid and other free fatty acids that cause tissue damage via production of oxygen radicals and prostaglandins.

Other effects within the cell influence DNA and RNA production, hence inhibiting protein production. This may explain why cellular and clinical recovery is partial, even with restoration of ionic equilibrium and near-normal ATP levels after successful reperfusion. Necrosis is thought to occur in the core of the cerebral infarct following acute vascular occlusion, with further neurodegeneration occurring more slowly in the penumbra, by apoptosis or release of various immunological mediators.[2]

EXTRACELLULAR EFFECTS

Leucocytes are thought to be major contributors to reperfusion injury in that:

- they may plug up small capillaries under conditions of low blood flow and prevent reflow in certain areas, thus hindering restoration of perfusion
- they may enhance production of oxygen radicals and begin a cascade of inflammatory mediators, which may potentiate cell destruction in injured tissue.

These mechanisms result in tissue oedema, which may affect the core lesion by narrowing blood vessels and worsening chances of reperfusion. Local mechanical compression of tissue or its blood supply can cause deterioration in neighbouring tissue. The alteration in volume is of extreme importance in the adult brain because the cranial vault is non-distensible, preventing accommodation to an expanding lesion. This will impede CBF both locally and globally.

Hypoxic/ischaemic insults are rarely predictable, so that the process is usually well established when clinicians intervene. It is therefore highly likely that the injury will be only partially remediable.

MANAGEMENT

In neurological injury, the initial aims are to provide basic support. Assessment of the airway and respiration are the first priority, closely followed by optimisation of the circulation.

In cases of head trauma, it is very important to prevent secondary brain injury. Reviews of intensive care practice have resulted in recommendations for treatment in this group of patients.[3] These involve:

- institution of systemic and neurological monitoring
- early treatment of hypoxia, hypotension, hyperthermia, hyperglycaemia and intracranial hypertension
- maintenance of CPP.

Following stroke, it is also important to optimise homeostasis and address any extreme hypertension, hyperglycaemia, hyperthermia and intracranial hypertension, as these are independent factors of a poor prognosis.

HYPOXIA

This is defined as O_2 saturation <90% or a P_{O_2} <8 kPa. Irrespective of aetiology, hypoxia occurs when impaired consciousness and loss of airway reflexes cause partial or complete airway obstruction, hypoventilation, aspiration pneumonia or atelectasis.

In mechanically ventilated patients with traumatic brain injury, settings should aim to achieve a $P_{O_2} \geq 10$ kPa

and a P_{CO_2} of 4.5–5.0 kPa. It has been suggested that high PEEP≥15 cmH_2O may decrease cerebral venous drainage by increasing intrathoracic pressure, thus increasing cerebral blood volume and intracranial pressure.[3] In the brain-injured patient with ALI/ARDS these requirements pose a ventilatory challenge as they tend against those employed for lung protection.

In patients who have had an acute stroke oxygen saturations should be kept greater than or equal to 92%.[4] In stroke patients who require intubation either for decreased GCS or hypoxia, prognosis is poor with about 50% being dead within 30 days of the clinical event.[5]

There is currently no evidence for the use of hyperbaric oxygen in the treatment of stroke or traumatic brain injury,[6,7] but there is continuing interest in the early application of normobaric hyperoxia treatment in these two conditions as guided by cerebral tissue oxygen monitors.[8]

BLOOD PRESSURE CONTROL

Fluctuating haemodynamics occur in the majority of patients following an acute brain injury. The therapeutic type, timing and extent of intervention to correct this instability are still being debated, but there appears to be growing evidence that the aetiology of the brain injury should be clarified prior to initiating any treatment.

In stroke patients the mechanism and effects of blood pressure elevation are not well understood. Most experts would not advocate antihypertensive treatment in the acute phase unless the blood pressure is particularly high. Currently hypertension (systolic blood pressure >180 mmHg (24 kPa) or diastolic blood pressure >110 mmHg (14.6 kPa)) is a contraindication to thrombolysis, based on the trials involving rtPA in which the blood pressure was lowered prior to treatment.[9,10]

The International Stroke Trial involving patients with ischaemic stroke found that systolic blood pressures >200 mmHg (26.6 kPa) and <120 mmHg (16 kPa) were associated with poor clinical outcome, systolic blood pressures between 140 and 160 mmHg (18.6–21.3 kPa) were associated with the best outcome and reducing the systolic blood pressure of patients who were in this range was associated with a 17.9% increase in mortality for every 10 mmHg below 150 mmHg (20 kPa).[11.]

Conversely, in haemorrhagic stroke, The Intensive Blood Pressure Reduction in Acute Intracerebral Haemorrhage Trial (INTERACT) suggested early blood pressure reduction within 6 hours of diagnostic imaging. Patients whose systolic blood pressure was reduced to 140 mmHg (18.6 kPa) compared with a standard group of 180 mmHg (24 kPa) showed a reduction in haematoma growth over the subsequent 72 hours.[12] Phase III of this trial, INTERACT 2 aims to look at the long-term functional benefits of this intervention.

Following traumatic brain injury hypotension (systolic blood pressure <90 mmHg (12 kPa)) is more common and significantly associated with increased mortality.[3] It is often caused by cardiogenic, hypovolaemic or neurogenic shock from other injuries rather than the brain injury itself. Fluid and blood product resuscitation should be employed along with vasopressors if appropriate and guided by systemic invasive monitoring. Hypertension in traumatic brain injury should be treated cautiously. Secondary brain injury hypertension may increase ICP through vasogenic cerebral oedema but it may also be a physiological response to poor cerebral perfusion. Rapid reduction of blood pressure may worsen cerebral ischaemia and treatment of high systolic blood pressure (>180 mmHg (24 kPa)) should not occur until another causes have been excluded and neurospecific monitoring employed.[3]

HYPERGLYCAEMIA

Hyperglycaemia has been associated with increased mortality and reduced functional outcome irrespective of brain injury aetiology or a diabetic history.[13] Proposed explanations for this are:

- potential direct hyperglycaemic toxicity to the ischaemic brain
- decreased levels of insulin and its peripheral uptake thus increasing cerebral glucose availability and potential impairment of endothelial-dependent vasodilatation
- possible dysglycaemia, which is associated with vascular disease and endothelial dysfunction, both of which may exacerbate ischaemic damage at the time of stroke
- increased risk of a hypercoagulable state, with decreased plasma fibrinolytic activity, which may delay reperfusion and increase haemorrhagic infarct conversion in tissue plasminogen activator-treated patients.[14]

For these reasons many studies have investigated the effects of tight glucose control in stroke and traumatic brain injury, unfortunately with disappointing results.

The Cochrane review, ‘Insulin for glycaemic control in acute stroke’ compared tight and ‘standard’ glucose control employed within 24 hours of the stroke, in terms of death and dependency. There was no difference between the groups but patients in the intervention group experienced significantly more symptomatic and asymptomatic hypoglycaemic episodes.[15] The INSULINFARCT trial compared intravenous with subcutaneous insulin treatment on post-stroke glycaemic control and MRI-imaged cerebral infarct size. Again there was no difference in functionality, death or serious adverse events between the two groups. There was an association in the intravenous insulin group with increased infarct size.[16] Thus there is no evidence for intensive insulin therapy in hyperacute ischaemic stroke.

There are studies, albeit with small numbers of patients, using cerebral microdialysis to assess cerebral metabolism, which infer that tight glucose control reduces extracellular cerebral glucose availability, causes a cerebral metabolic crisis and is associated with increased mortality.[17,18]

TEMPERATURE CONTROL

An increased temperature increases cerebral metabolism, oxygen requirements, CBF and ICP. Hyperpyrexia following acute stroke adversely influences stroke severity, infarct size, functional outcome and mortality.[19] A raised temperature should, therefore, be treated aggressively using ice packs, cooling blankets, or intravascular cooling systems if available. Any evidence of infection should be identified early and treated with appropriate antibiotics.

Potential mechanisms by which hyperthermia worsens cerebral ischaemia may include:

- neurotransmitter and oxygen free radical production
- blood–brain barrier failure
- damaging depolarisations in the ischaemic penumbra
- impaired recovery of energy metabolism
- cytoskeletal proteolysis.[20]

Hypothermia has been known for years to offer protection. Classically the primary neuroprotective effect of hypothermia has been attributed to reduction in cerebral metabolic rate and hence oxygen consumption with improved glucose utilisation. Animal models have demonstrated the beneficial effects of hypothermia on secondary injury, namely reduced cerebral oedema, reduced ischaemia and reperfusion injuries, decreased infarct size, decreased excitatory neurotransmitters, less acidaemia and preservation of the blood–brain barrier vascular integrity.[21,22] Complications of hypothermia include hypotension, pneumonia, electrolyte derangement, cardiac arrythmias and coagulopathy.

In contrast to preventing hyperthermia, the use of induced hypothermia is more complex. It has been used extensively in cardiac surgery to provide optimal operating conditions and protection against organ ischaemia. Induced hypothermia (28–30°C) for coronary artery bypass is commonplace and deep hypothermia (<20°C) allows prolonged circulatory arrest for complex surgical procedures such as aortic arch repairs.

Two randomised clinical trials of induced hypothermia after witnessed out-of-hospital ventricular fibrillation cardiac arrest demonstrated improved survival and neurological outcome after 12 or 24 hours of hypothermia at 32–34°C (see online Appendix 9).[23,24] This has led to recommendations by the International Liaison Committee on Resuscitation.[25]

The benefits of therapeutic hypothermia in traumatic brain injury and ischaemic stroke are unproven. Therapeutic hypothermia for treatment of TBI was first used in 1943 without success. There have been many studies, meta-analyses and reviews that have looked at the effects of induced moderate hypothermia (above 30°C) on the outcome of patients with TBI in the last 20 years. Although the majority of studies have shown a decrease in ICP with cooling, there haven't been any proven benefits on outcome. The results have been inconclusive because of variations in methodology, patient numbers and demographics, centre cooling experience and adjuvant treatments to name but a few.[26,27] The European Society of Intensive Care Medicine study of therapeutic hypothermia (32–35°C) for ICP reduction after traumatic brain injury (EUROTHERM3235Trial) is currently recruiting. Its primary objective is to look at the effects of hypothermia on patient outcome at 6 months using the extended Glasgow Outcome Score (GOSE) questionnaire.[28]

Although therapeutic hypothermia is well established to improve survival and neurological outcome in global cerebral ischaemia following cardiac arrest, its benefits in focal cerebral ischaemia are not yet established. Clinical trials have studied pharmacological (antipyretic and anti-inflammatory agents) and physical ways of inducing hypothermia. Pharmacological ways of reducing temperature have been disappointing with no clinical benefit. Physical methods involve either surface or intravascular cooling. Surface cooling is often easier to apply but target temperature takes longer to reach (peripheral vasoconstriction) and prevention of shivering may require sedation and paralysis. Intravascular cooling is more effective, allows for surface warming thus reducing shivering but its invasive nature carries risks.[22] The rate of reaching target temperature, the duration of hypothermia and the rate of rewarming have been investigated in several trials. From clinical trials and experimental work done so far, early therapeutic hypothermia for 24–72 hours followed by slow rewarming appears to be the best combination for a promising neurological outcome.[22] EUROHYP-1 is a major phase III clinical trial and will be launched imminently.

REVASCULARISATION

Aims of treatment for focal cerebral ischaemia are:

- Start treatment as early as possible.
- Increase local CBF (fibrinolysis).
- Try to ameliorate ischaemic cascade (neuroprotection).

Ischaemic neuronal degeneration follows the onset of perfusion failure so that interventional therapy must begin immediately. Diagnostic imaging is required before using thrombolytic agents. For acute ischaemic stroke the National Institute of Neurological Disorders and Stroke (NINDS study) suggested efficacy if intravenous thrombolytic therapy is initiated within the first

3 hours of stroke symptoms (using recombinant tissue plasminogen activator).[29] In fact subgroup analysis within the study showed improved outcome the earlier the thrombolysis was given.

Current issues in implementing this treatment include:

- diagnosis, including imaging within this timeframe
- the potential risks of thrombolysis and the need for specialist stroke services for monitoring and reimaging as necessary
- accurately selecting patients eligible for thrombolysis.

'TRIPLE H' THERAPY

Hypervolaemic haemodilution and deliberate hypertension or 'triple H' therapy has been an accepted but controversial intervention to prevent delayed cerebral ischaemia secondary to vasospasm following subarachnoid haemorrhage. Cerebral vasospasm usually develops from about 72 hours after the primary insult and peaks over the subsequent 2 weeks before resolving spontaneously at days 21–28. As the efficacy of 'triple H' therapy is still unproven and is not without its complications there has been a therapeutic shift towards euvolaemia and induced hypertension.[30,31]

INTRACRANIAL PRESSURE

Raised ICP can cause global ischaemia. Treating ICP requires knowledge of the three compartments contributing to ICP within a fixed cranium:

- blood
- relatively non-compliant brain tissue
- cerebrospinal fluid (CSF).

The relationship between ICP and intracranial volume is described by a non-linear pressure–volume curve. At lower intracranial volumes the ICP remains low and reasonably constant. Any increases in intracranial volume are compensated for by decreases in intracerebral blood or CSF volume. If greater intracranial volumes persist, this compensation is lost and ICP rises considerably, despite relatively small increases in intracerebral blood volume. Eventually at high levels of ICP cerebrovascular responses are lost, ICP equals MAP and CPP is very low.

To maintain adequate cerebral perfusion, treatment should be targeted at ensuring an adequate perfusion pressure and a reduction in ICP. MAP should be raised to a level at or above the usual pressure for that patient, within a patient-specific zone of pressure autoregulation. If the majority of the vasculature is autoregulating, raising the blood pressure may decrease vascular diameter and reduce blood volume within the cranium. If the cause of the raised ICP cannot be corrected (e.g. blood clot or brain tumour), then the focus should be to prevent secondary injury around the lesion. An increased ICP can cause further ischaemia, and a reduction in ICP may facilitate adequate perfusion to areas at risk. Whenever possible, the offending compartment should be treated promptly (e.g. tumour removal, blood evacuation, drainage of hydrocephalus and, on occasion, craniectomy). If this is not advisable, reducing the relative volumes of other compartments may improve compliance overall and reduce the ICP.

MONITORING OF ICP (FIG. 52.3)

ICP-monitoring devices have been ranked by the Brain Trauma Foundation[32] on their accuracy, stability and ability to drain CSF. Intraventricular and intraparenchymal catheter tip microtransducer catheters are the most commonly used. Subdural, subarachnoid and epidural devices are now rarely used.

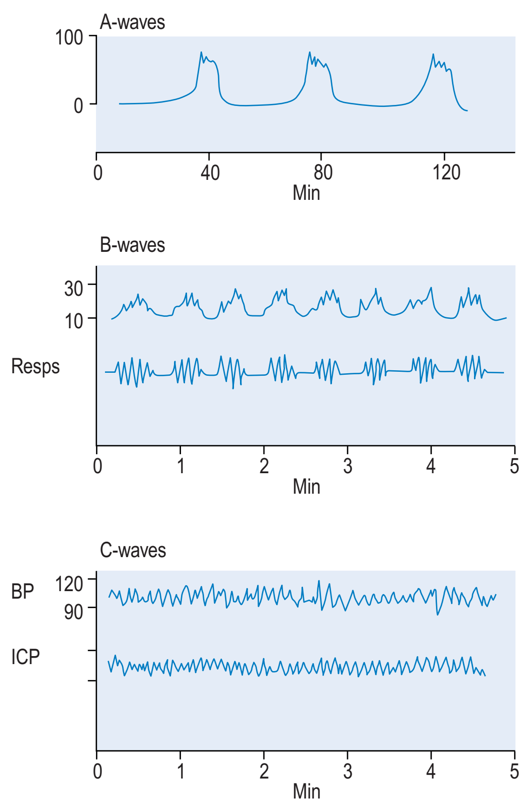

Figure 52.3 Intracranial pressure (ICP) waveforms. A-waves are plateau waves of 50–100 mmHg, sustained for 5–15 minutes, associated with raised ICP and compromised cerebral blood flow. B-waves are small changes in pressure every 0.5–2 minutes, often associated with breathing patterns and possibly due to local variations in the partial pressure of oxygen and carbon dioxide. C-waves are low-amplitude oscillations with a frequency of about 5 per minute, associated with variation in vasomotor tone. Resps = respirations; BP = blood pressure.

INTRAVENTRICULAR DEVICES

This is the gold standard of ICP measurement and is capable of measuring global ICP. The pressure transducers can either be external and attached to a fluid-filled catheter or internal, within the catheter lumen. Insertion is into the lateral ventricle usually via a small right frontal burr hole. The external auditory meatus is used as the reference point.[33] This device allows CSF sampling for culture or therapeutic drainage, the administration of antibiotics and the ability to recalibrate following insertion. The main disadvantage is the high infection rate associated with their use.[32,33] Infection rates increase significantly after 5 days of catheter insertion and with repeated use of the device's flushing system. The use of antibiotic-impregnated catheters may lower the infection rate. Air, blood, tissue debris and ventricular collapse can all adversely affect measurement.

INTRAPARENCHYMAL DEVICES

ICP can be measured by either a miniature strain gauge pressure transducer mounted at the end of a thin catheter or by a fibreoptic cable, which directs light to a miniature mirror at the end of the cable. The catheter can be placed in brain tissue or the subdural space via a skull bolt, burr hole or neurosurgical procedure. These monitors are advantageous when lateral ventricles have collapsed secondary to raised ICP. This system is not dependent on fluid coupling for pressure transduction so waveform damping and artefact are avoided. The infection rates are very low. Its main disadvantages include lack of recalibration in vivo, a tendency for baseline drift requiring transducer replacement, the inability to drain CSF and the ability to measure only localised pressure, which may not be representative of the global ICP.[33,34]

Alternative invasive ICP monitoring includes epidural, subarachnoid and subdural devices, although these are not as accurate. All invasive ICP-monitoring devices are associated with a risk of infection and parenchymal damage with the potential for parenchymal and subdural bleeding. Less-invasive methods of measuring ICP are being investigated. These include infrared spectroscopy, visual evoked potentials, transcranial Doppler and with perhaps the most promising correlation to invasive measurements, optic nerve sheath diameter ultrasound. When it is not possible to insert or interpret an ICP-monitoring device clarification should be sought by computed tomographic (CT) or MRI scanning.

REGULATION OF INTRACRANIAL PRESSURE

BRAIN COMPARTMENT

Reduction in the parenchymal compartment depends on removal of either free water or the lesion causing the raised ICP.

Free water must be moved across an intact blood–brain barrier. Mannitol is recommended as first-line osmotic agent for elevated ICP, although this is controversial. Two meta-analyses have indicated that hypertonic saline is more effective than mannitol for the treatment of raised ICP caused by differing pathologies.[35,36] Choice of agent may be influenced by their individual properties: whereas hypertonic saline improves volume status, cardiac output, regional blood flow and CSF absorption, mannitol may improve microvascular cerebral blood flow, reduce blood viscosity, reduce CSF production and inhibit apoptosis. Further evaluation is required.

Removal of tumour or blood clot, drainage of abscesses and extirpation of infarcted brain are all therapies aimed at improving compliance. Mounting evidence now suggests that there is a penumbra of functionally impaired but potentially reversible neuronal injury surrounding a haematoma. Indications for clot removal, despite numerous studies performed over the last four decades, has been controversial. The Surgical Trial in Intracerebral Haemorrhage (STICH) compared early surgical evacuation (within 24 hours) of haematoma with initial conservative treatment, but found no significant difference in outcomes between the two treatments. However, a subgroup analysis indicated that patients with superficial haematomas and without an associated intraventricular haemorrhage may do better with early surgical removal.[37] For these reasons STICH II is underway recruiting a more select group of patients with superficial lobar haematomas to compare conservative versus surgical treatment.[38]

The rationale for removing part of the skull is to decompress the brain, prevent cerebral herniation and thus reduce ICP, a significant predictor of patient outcome. The benefits of craniectomy versus medical treatment for refractory raised ICP in TBI remain uncertain. The Decompressive Craniectomy in Diffuse Traumatic Injury Trial (DECRA) compared bifrontotemporoparietal decompressive craniectomy with standard medical treatment for the effects on patients with refractory raised ICP and their functional outcome. The patients in the surgical group had fewer days with a raised ICP, required fewer interventions to control their ICP and had a shorter length of ICU stay. Unfortunately the 6-month outcome in the surgical group was unfavourable as measured by the Extended Glasgow Outcome Scale and hypotheses for this included axonal stretch and injury, changes in cerebral blood flow and metabolism and differing surgical techniques.[39] The Randomised Evaluation of Surgery with Craniectomy for Uncontrollable Elevation of raised Intra-Cranial Pressure trial (RESCUEicp) is still recruiting to evaluate whether decompressive craniectomy improves outcome in those patients whose raised ICP is refractory to treatment at a higher ICP.[40]

The outcome of craniectomy for ischaemic stroke is much more favourable. Massive middle cerebral artery

stroke, 'malignant' stroke, has a very high mortality due to the very extensive cerebral oedema, raised ICP and resultant herniation. Surgical intervention succeeds where medical treatment fails, reducing mortality from 80% to 20%.[40] Three European trials, Decompressive Craniectomy in Malignant Middle cerebral Artery Infarction (DECIMAL),[41] Decompressive Surgery for the Treatment of Malignant Infarction of the Middle Cerebral Artery (DESTINY)[42] and Hemicraniectomy After Middle Cerebral Artery infarction with Life-threatening Edema Trial (HAMLET),[43] indicated that surgery is not just life-saving but if done early (within 48 hours) has benefits on the severity of functional disability.[40]

The role of decompressive craniectomy in subarachnoid haemorrhage is still uncertain. Loss of cerebral perfusion is mainly due to vasospasm, a physiological response unlikely to be reversed by expanding intracranial space.[44]

BLOOD COMPARTMENT

Although a small component of intracranial volume, the blood compartment is the most compliant. Reduction in blood volume is useful in the treatment of raised ICP, especially in the acute setting. Hypoxia and hypercarbia can lead to hyperaemia and an increase in cerebral blood volume, potentially worsening ICP. Induced hypocarbia is accompanied by a fall in global CBF, which may result in critical ischaemia and a worsened outcome particularly if applied within the first 24 hours. The Brain Trauma Foundation's recommendation is that hyperventilation should be used only as a temporising measure to reduce raised ICP and that ideally some form of neurospecific oxygen monitoring should be employed. Secondary treatment for raised ICP should be instituted as soon as possible.

CEREBROSPINAL FLUID COMPARTMENT

CSF drainage can be used to reduce ICP but is only possible if there is a ventricular catheter in place. Care is taken regarding the route and rate of CSF drainage to avoid herniation of a mass lesion, either towards the other side of the brain or through the tentorium. Less-invasive methods of measuring ICP are being employed. However, the Brain Trauma Foundation guidelines for the management of severe head injury provide some evidence supporting the increased use of CSF drainage for ICP control.[45]

ANAESTHETIC AGENTS

Barbiturates have been used for decades for controlling raised ICP. Barbiturate-mediated neuroprotection was initially attributed to suppression of cerebral metabolic rate, but more recently to coupling of CBF to regional metabolic demands, the blockade of glutamate receptors and sodium channels, inhibition of free radical formation and potentiation of GABAergic activity.[46,47] Barbiturates are now less commonly used in head-injured patients but can play a role in those patients who have intractable intracranial hypertension.

Propofol has been shown to be neuroprotective in vivo, in focal and global models of cerebral ischaemia. It decreases cerebral metabolic rate and hence CBF. It has been shown to have antioxidant properties, potentiate $GABA_A$-mediated inhibition of synaptic transmission and inhibit glutamate release. It delays neuronal death by being a free radical scavenger, preventing lipid peroxidation and modulating apoptosis-regulating proteins.[46,48] Its side-effects include hypotension with a reducing CPP and hyperlipidaemia when an infusion of 200 μg/kg per min is used to produce burst suppression.[48] This latter problem has been lessened by the introduction of a more concentrated formulation.

Inhalational agents have significant neuroprotective effects but the precise mechanism by which they reduce cerebral injury is unclear.[48] It is possible that isoflurane may attenuate excitotoxicity by inhibiting glutamate release and its postsynaptic responses at both anaesthetic and EEG burst suppression concentrations. The neuroprotection provided by volatile agents may also be attributable to their effect at $GABA_A$ receptors and ability to reduce the sympathetic vascular response to ischaemia. Certainly their effect on reducing cerebral metabolic rate is not sufficient to explain their neuroprotective properties.[46,47] These potential benefits in adults are offset by recent studies which have suggested that in neonatal animal studies there may be disturbing increases in cerebral apoptosis, although this has yet to be confirmed.

Nitrous oxide exhibits the neuroprotective and neurotoxic features of an NMDA antagonist. Studies, however, have shown that, when combined with an opioid (e.g. fentanyl), its neuroprotective effect during incomplete cerebral ischaemia is still inferior compared with volatile agents.[47]

Midazolam reduces the cerebral metabolic rate for oxygen, CBF and volume. It does not produce burst suppression or an isoelectric EEG, even in large doses.

Neuromuscular blockade is often used in head-injured patients to prevent any coughing on the tracheal tube and subsequent rise in ICP. Their use is not associated with better outcome despite the improvements in ICP control.

CALCIUM ANTAGONISTS

The influx of calcium from the extracellular space and from intracellular organelles has been implicated as

the common mediator of cell death from a variety of causes. Calcium antagonists were among the first neuroprotective agents studied to prevent cerebral ischaemia. Despite the effects seen in animal models, human studies in both global and focal ischaemia have been disappointing. Two large trials of intravenous nimodipine in patients with acute ischaemic stroke were terminated early as neurological and functional outcome were significantly poorer in the nimodipine group.[49,50] A close relationship was found between a reduction in diastolic and mean blood pressure in the group treated with nimodipine and an unfavourable neurological outcome. A review of 29 randomised acute stroke trials involving calcium antagonists concluded that the use of calcium antagonists could not be justified in patients with ischaemic stroke and that, although the published trials showed no overall effect on death and dependency, unpublished trials were associated with a statistically significant worse outcome.[51] Nimodipine, however, has become the standard prophylactic treatment for cerebral vasospasm after subarachnoid haemorrhage, with a consequent decrease in cerebral infarction and better patient outcome.[52] Benefits appear to be due to an effect on smaller penetrating vessels not seen by angiography, or a neuroprotective effect at the cellular level, rather than cerebral vasodilatation identifiable by angiography.

Nimodipine was shown to be neuroprotective in head-injured patients with traumatic subarachnoid haemorrhage.[53] Regrettably, further studies to test the neuroprotective effect of nimodipine in severely head-injured patients with traumatic subarachnoid haemorrhage (including the multicentre study, HIT 4) failed to confirm the beneficial effects of nimodipine. A small group of patients with a Glasgow Coma Score <9 did appear to be a have a better outcome in the nimodipine-treated group.[54] However, a recent systematic review concluded that there was no beneficial effect on outcome.[55] Its use therefore remains contentious.

STEROIDS

Glucocorticoids were used for over 30 years in the treatment of raised ICP from head injury despite the fact that randomised trials had failed to demonstrate their effectiveness reliably. They were thought to decrease cerebral oedema associated with breakdown of the blood–brain barrier (i.e. vasogenic oedema), decrease CSF production, attenuate free radical production and show improvement in central nervous system function in patients with brain tumours and abscesses.[56,57]

The Corticosteroid Randomisation After Significant Head injury (CRASH) trial[58] investigated the effects of a 48-hour infusion of methylprednisolone on death within 14 days or disability at 6 months in 10 008 adults with clinically significant head injury. The trial was stopped early as, at interim analysis, the steroid-treated subjects had significantly higher all-cause 2-week mortality (21.1% versus 17.9%, p=0.0001). The 6-month mortality was also higher in steroid-treated subjects (25.7% versus 22.3%, p=0.0001), with a trend toward increases in the combined end-point of death or severe disability (38.1% versus 36.3%, p=0.08). In neither report did the results differ by injury severity or time since injury.[58] The cause for the increased mortality is unclear.

In subarachnoid and primary intracerebral haemorrhage, corticosteroids have also been commonly used. In 2005, a Cochrane Review concluded that there was no evidence to support the use of mineralocorticoids or glucocorticoids in subarachnoid haemorrhage or to support the use of glucocorticoids in primary intracerebral haemorrhage. Corticosteroid use may also be associated with adverse events.[59]

TRANEXAMIC ACID

Tranexamic acid has been shown to safely reduce patient blood loss during elective surgery. The Clinical Randomisation of an Antifibrinolytic in Significant Haemorrhage study (CRASH II) compared the effects of an early short course of tranexamic acid versus placebo on mortality in trauma patients who were at risk of significant blood loss. Cause of death was categorised into bleeding, vascular occlusive events (myocardial infarction, stroke and pulmonary embolism), multiorgan failure, head injury and other. All-cause mortality was significantly reduced with tranexamic acid, but particularly in the bleeding category.[60] CRASH III aims to quantify the effects of tranexamic acid versus placebo on death and disability in trauma patients who have suffered intracranial bleeding.

Optimal cerebral management of patients suffering an acute brain injury remains controversial. Certainly it appears that early clarification of the cause of the brain injury and access to specialist centres is increasingly important for guiding treatment and improving outcome (e.g. blood pressure control, thrombolysis, pharmaceutical intervention and rehabilitation). Unfortunately both old established and new experimental treatments have still yielded disappointing results or safety concerns when applied on a large scale. There are however some new and amended therapeutic interventions which appear promising and are currently under investigation. Hopefully the outcome of these will add to our knowledge and help to improve the management of patients with cerebral injury.

Brain death

Martin Smith

The determination of death by neurological criteria, or brain death, has been recognised in many countries for more than 40 years. Brain death describes a state of irreversible loss of brain function, including brainstem function, that provides a professional and legal framework for the withdrawal of therapies, including mechanical ventilation, from an individual who is (brain) dead. A further benefit for society is the availability of organs for transplantation from heart-beating donors.

HISTORICAL PERSPECTIVE

In the 1950s, developments in critical care led to the prospect of somatic function being sustained by mechanical ventilation long after brain function had ceased in patients who did not fulfil the historical criteria for death (i.e. the absence of a heart-beat). This state of unconsciousness, brainstem areflexia and the absence of spontaneous respiration and cortical electrical activity was described in 1959 by Mollaret and Goulon as 'le coma dépasse' – literally a state beyond coma.[1] Although it was agreed that it was futile to maintain treatment in such patients, it was not until the development of heart transplantation, and the associated importance of determining death in heart-beating donors prior to organ retrieval, that the first widely accepted standard for the confirmation of brain death was published by an ad hoc Committee of the Harvard Medical School in 1968.[2] Whilst these initial recommendations defining brain death were temporally associated with advances in transplantation, the concept of brain death was not primarily designed to facilitate donation. Rather it was developed to allow the withdrawal of therapies from an individual who has died and who can no longer conceivably derive benefit from them.[3]

The 'Harvard criteria' defined brain death in terms of the irreversible loss of function of the whole brain and described a clinical picture of lack of responsiveness, absence of brainstem reflexes and apnoea – a definition that remains largely unchanged today. In the following year the committee indicated that brain death could be diagnosed on clinical grounds alone, without the need for a confirmatory electroencephalogram (EEG), so long as certain aetiological preconditions were present.

In the UK in 1976 the Conference of Medical Colleges and their Faculties took a slightly different approach and concluded that permanent functional death of the *brainstem* constitutes brain death and that this could be diagnosed clinically in the context of irremediable structural brain damage after certain specified conditions had been excluded.[4] A set of guidelines and clinical tests for the diagnosis of brainstem death were established and these have become the foundation of modern practice. A subsequent memorandum in 1983 made additional recommendations about the timing of the clinical tests and who should perform them. It also confirmed that there may be circumstances in which it is impossible or inappropriate to carry out every one of the tests and that it is for the doctor at the bedside to determine that the patient is dead.

DEFINITIONS OF BRAIN DEATH

Death is not a single event but a process that leads progressively to the failure of all functions that constitute the life of the human organism. Once a threshold of irreversibility has been reached, and brain death is such a point, it is not necessary to wait for the death of the whole organism for the inevitable consequence of its biological death to be certain.[3] There is widespread acceptance that human death is ultimately death of the brain and that this crucially involves the irreversible loss of the capacity for consciousness combined with the irreversible loss of the capacity to breathe. These elements represent the most basic manner in which human beings interact with their environment.

Two modes of death are described – cardiorespiratory arrest and brain death – but this distinction is artificial because cardiorespiratory arrest results in inevitable death of the whole person only if the period of arrest is long enough to result in irreversible damage to the brain, particularly to the brainstem. The neurons of the brainstem are the most resistant to anoxia so shorter periods of cardiac or respiratory arrest may result in retention of the ability to breathe but survival with differing, and often severe, degrees of cortical damage.

CAUSES OF BRAIN DEATH

Brain death results from massive brain swelling, a sustained rise in intracranial pressure equal to or above systemic arterial pressure causing cessation of cerebral circulation and brainstem herniation. Around 5% to 10% of all comatose patients admitted to intensive care units become brain dead. The principal causes in adults are traumatic and haemorrhagic brain injury, and severe cerebral hypoxia–ischaemia.

After the onset of brain death, brainstem reflexes are lost sequentially in a craniocaudal direction. This process may take several hours to become complete but finally results in apnoea due to failure of the medulla oblongata. Because of the fundamental controlling role of the brainstem, myocardial and other systemic physiological functions deteriorate after the onset of brain death and, without cardiovascular support, brain-dead patients progress to asystolic cardiac arrest within a relatively short time.[5]

WHOLE BRAIN AND BRAINSTEM DEATH

Brain death is confusingly defined in two different ways based on 'whole' brain and 'brainstem' formulations. The Uniform Determination of Death Act states that 'an individual who has sustained irreversible cessation of all functions of the entire brain, including the brainstem, is dead' and gives equivalence to death determined by neurological and cardiovascular criteria.[6] This whole brain formulation is the standard for the determination of death by neurological criteria in many parts of the world, including the USA and most European countries, and requires confirmation of the loss of *all* brain function, including the brainstem.

On the other hand, the diagnosis of brainstem death, such as that used in the UK, does not require confirmation that all brain functions have ceased, but rather that none of those functions that might persist should indicate any form of consciousness.[7] In determining brainstem death, confirmation of the irreversible loss of the capacity for consciousness combined with the irreversible loss of the capacity to breathe relies on the fact that key components of consciousness and respiratory control, the reticular activating system and nuclei for cardiorespiratory regulation, are located in the brainstem.

Early arguments to support the concept of brain death relied on the brain as the central integrator of somatic function, but brain dead patients may exhibit levels of somatic integration that can persist for some time. A 'loss of personhood' was therefore proposed as an alternative rationale because the loss of certain key human functions, such as the ability to be conscious or apply reason, is deemed to be sufficient for the philosophical and ethical justification, as well as the legal determination, of death.[8] In the USA in 2008, the President's Council on Bioethics concluded that it is the 'ability to conduct the vital work of a living organism – the work of self-preservation, achieved through the organism's need-driven commerce with the world' that supports the continued use of brain death as a valid determinant of human death.[9] An individual with irreversible loss of brainstem function who has no drive to breathe, and who can neither perceive nor interact with their environment to meet their basic requirement for oxygen and other nutrients, can no longer be considered to be living. In this way brain death is equivalent to the death of the individual as a whole.

DIAGNOSIS OF BRAIN DEATH

The majority of countries have followed the lead of the USA and the UK in specifying that the clinical diagnosis of brain death is sufficient for the determination of death in adults.

The diagnostic algorithm has three sequential but interdependent steps. Certain preconditions and exclusions must be fulfilled before clinical tests of brainstem function are performed.[7]

PRECONDITIONS

- The patient should be in apnoeic coma (i.e. unresponsive and dependent on mechanical ventilation).
- The cause of coma must be known and due to brain damage that is consistent with the diagnosis of brain death.
- The underlying disorder that has led to this state must be established.

In all cases a cranial computed tomography scan is essential. Establishing the causative diagnosis is relatively straightforward in the case of head injury or intracranial haemorrhage but may take longer in coma arising from hypoxia or other causes.

EXCLUSIONS

Reversible causes of coma must be excluded (**Table 53.1**). The original Harvard criteria specifically required the exclusion of the effects of hypothermia and depressant drugs and, although these are consistently cited in modern recommendations, the thresholds for testing vary considerably between countries.[10]

CLINICAL TESTS

There is no evidence to define a minimum period of observation between the onset of apnoeic coma and clinical examination to ensure irreversibility.[11] Many countries recommend a minimum of 6 hours, whereas in others no minimum period is specified.[12] Most guidelines recommend a longer period of observation, typically 24 hours, in coma related to anoxic brain injury.

The clinical examination is designed to demonstrate the absence of brainstem reflexes and confirm the

Table 53.1 UK recommendations for the exclusion of potentially reversible causes of coma and apnoea

VARIABLE	REQUIREMENTS
Drugs	• Exclude sedative drug effects: – consider specific antagonists, e.g. naloxone, flumazenil – serum drug levels should be measured where assays are available – no consensus regarding the minimal concentration at which brain death can be diagnosed • Exclude residual effects of neuromuscular-blocking drugs: – presence of deep tendon reflexes – train-of-four present on peripheral nerve stimulation
Hypothermia	• Temperature >34°C
Cardiorespiratory	• Mean arterial blood pressure consistently >60 mmHg • Pa_{O_2} > 10 kPa • Pa_{CO_2} < 6.0 kPa • pH 7.35–7.45
Electrolytes	• Sodium 115–160 mmol/L • Potassium >2.0 mmol/L • Magnesium 0.5–3.0 mmol/L • Phosphate 0.5–3.0 mmol/L
Endocrine	• Hormonal assays if suspicion of myxoedema or Addisonian crisis

Box 53.1 Components of the clinical examination to confirm brain death in the UK

Cranial nerve examination
- Pupils are fixed and do not respond to light
  - no pupillary response to sharp changes in the intensity of incident light
  - the pupils do not need to be maximally dilated, simply unresponsive
- Absent corneal reflexes
- Absent oculo-vestibular reflex
  - no eye movements during or following slow injection of 50 mL ice-cold water over 1 minute into each external auditory meatus
  - clear access to tympanic membrane confirmed by direct inspection prior to testing
  - head at 30° to the horizontal plane unless contraindicated by unstable spine injury
- No motor response within cranial nerve distribution to adequate stimulation of any somatic area
  - supraorbital pressure often used as the stimulus
- Absent cough reflex
  - no response to a suction catheter inserted into the trachea to the carina
- Absent gag reflex
  - no response to stimulation (under direct vision) of the posterior pharynx with a spatula

Apnoea test
- Absence of respiratory effort observed for >5 min
  - Sp_{O_2} must be maintained >95% throughout
  - cardiovascular stability during the test
  - Pa_{CO_2} must rise to >6.5 kPa (>50 mmHg) (pH<7.40) confirmed by arterial blood gas analysis

presence of persistent apnoea, and should be performed only when the preconditions and exclusions have been met.

CRANIAL NERVE EXAMINATION

A rigorous clinical examination of brainstem reflexes must be undertaken to confirm the diagnosis of brain death (**Box 53.1**). The clinical tests are designed to be easy to perform at the bedside, require no special equipment and have unequivocal results.

Confirmation of the absence of the oculo-cephalic reflex ('doll's-eye' movements) is not included in UK criteria but is part of the protocol in some countries. The presence of this reflex confirms that brainstem function persists and that further tests are inappropriate. Facial trauma or obstruction to external ear canals may make assessment of brainstem reflexes difficult, but injury preventing bilateral examination of some reflexes does not invalidate the diagnosis of brain death.

APNOEA TEST

Confirmation of apnoea is required by all guidelines but the end-points are inconsistent.[13] The overall aim is to produce an acidaemic respiratory stimulus (pH<7.4) in the presence of normoxia and ardiovascular stability. This applies even in those with chronic respiratory disease, although the Pa_{CO_2} required to achieve the end-point may be higher. To minimise the risk of further damage to potentially recoverable brain tissue, the apnoea test should only be performed after the absence of brainstem reflex activity has been confirmed. The following method describes a safe method for conducting the apnoea test in the UK.

- Pre-oxygenate with 100% oxygenation – ensure Sp_{O_2} > 95%.
- Reduce minute ventilation until E_{TCO_2} 6.0 kPa (45 mmHg) and pH is 7.4.
- Disconnect from the ventilator and maintain apnoeic oxygenation delivering oxygen by bulk flow using a re-breathing circuit and CPAP.
- Sp_{O_2} should remain >95% with cardiovascular stability (MAP>60 mmHg) throughout the procedure.
- Confirm a further rise in Pa_{CO_2} of more than 0.5 kPa (4 mmHg) (Pa_{CO_2} > 6.5 kPa (48.8 mmHg)) and pH<7.4 with blood gas analysis. (Pa_{CO_2} rises at about 3 mmHg/min or 0.5 kPa). In some countries, including Australia, the level required is >60 mmHg (8kPa) or >20 mmHg (2.7kPa) above the baseline level in those with chronic hypercapnia.
- Observe for the absence of respiratory activity for >5 minutes.

Following completion of the apnoea test the ventilator should be reconnected and normal minute ventilation resumed to allow return of acid–base variables to their pre-test levels.

TIMING AND REPETITION OF CLINICAL TESTS

More than one set of clinical tests is required in many jurisdictions to minimise the likelihood of errors in diagnosis.[10] However, after more than 30 years of applying clinical criteria for the diagnosis of brain death, there have been no cases of a response during the second examination in a patient who has satisfied the clinical criteria for brain death during the first. Where two sets of tests are required there is often no specified time interval between them. In the original Harvard criteria the two clinical examinations were separated by 24 hours but subsequent US guidance recommends that they may be repeated after 6 hours.[11] In the UK, the second set of tests may be performed as soon as arterial blood gas values have normalised following the first apnoea test.[7] The legal time for certification of death is often that of the initial testing but in some countries, such as Australia, the time of death is the time of the second confirmatory examination.

The number of doctors required to determine brain death varies. In most jurisdictions a single doctor is sufficient, but in the UK, Australia and some states in the USA two medical practitioners are required.[12] There are specific requirements for the base specialty of the doctors in some countries, whereas relevant competencies are defined in others. To avoid any conflict of interest, those diagnosing brain death are usually required to have no involvement with organ transplantation.

CONFIRMATORY TESTS

Clinical tests remain the gold standard for the diagnosis of brain death but confirmatory tests may have a place when the preconditions for clinical testing are unmet or where clinical testing cannot be completed. An alternative view argues that confirmatory tests have no role because the determination of brain death based on a comprehensive clinical examination is robust and, if clinical tests cannot be completed, support should be withdrawn on the grounds of futility.[14] The relevance of confirmatory tests varies between jurisdictions; patients with preserved cortical electrical activity or intracranial blood flow can be considered to be dead in countries that utilise a brainstem approach but not in those that apply a whole brain concept to the diagnosis of brain death.

Confirmatory tests are not specifically required in the UK, Australia or New Zealand but are required by law in some European countries.[7,12] US guidance recommends ancillary tests only where a clinical diagnosis cannot be made, but there is wide variability in their choice and application.[11]

Confirmatory tests fall into two main categories: those that assess cerebral blood flow (CBF) and those that evaluate the brain's electrophysiological activity.[15]

ASSESSMENT OF CEREBRAL BLOOD FLOW

Investigations of CBF are independent of confounding variables such as sedation, metabolic disturbance or hypothermia. The presence of residual CBF does not preclude a diagnosis of brain death and CBF methods of assessment may produce false-negative results, particularly after decompressive craniectomy or in the presence of skull fracture or cerebrospinal fluid drains.

Cerebral angiography

Four-vessel digital subtraction cerebral angiograph (DSA) is the gold-standard confirmatory test for brain death in some jurisdictions.[16] Following injection of contrast into both vertebral and carotid arteries, absence of flow beyond the foramen magnum will be confirmed in the posterior circulation and no flow beyond the petrosal portion of the carotid artery in the anterior circulation. Isolated or minimal filling necessitates repeat examination. DSA is invasive, time-consuming and readily available only in neuroscience units but it is reliable and easy to interpret. Newer imaging modalities, such as spiral CT angiography, are less invasive than DSA and accurately demonstrate the absence of CBF.

Cerebral tissue perfusion

Contrast-enhanced CT cerebral perfusion techniques are now widely available and their application in the diagnosis of brain death is likely to increase. Positron emission tomography is also accurate and unambiguous for the determination of absence of perfusion. Nuclear imaging techniques are also able to confirm absent cerebral perfusion but are not widely used in this context.

Transcranial Doppler ultrasonography

Transcranial Doppler (TCD) is a non-invasive bedside investigation used as a confirmatory test during the diagnosis of brain death.[17] Blood flow through both middle cerebral and vertebral arteries is compared with flow through extracranial vessels. Typical findings after brain death include diastolic reverberating flow and little or no forward systolic flow. There is significant operator dependence, and previous surgery or the presence of a ventricular drain may make waveform interpretation difficult. The absence of an acoustic window in some patients means that an absence of signal should not be taken as diagnostic of absence of blood flow.

ELECTROPHYSIOLOGY

The EEG is widely used as a confirmatory test in the diagnosis of brain death but specialist expertise is required for interpretation.[16] The absence of cortical

electrical activity during high-sensitivity recordings from 16 or 18 channels over 30 minutes is usually taken as confirmatory evidence of brain death. However, an isoelectric cortical EEG cannot confirm or exclude brainstem activity or the presence of viable neurons in other deep structures. Conversely, electrical activity in some cortical cells does not mean that the brain as a whole is alive. Confirmatory EEG examination is mandatory in many European countries and strongly recommended in some jurisdictions in the USA where loss of whole brain function must be confirmed. The EEG is affected by hypothermia and sedation and is therefore of limited value in circumstances where prolonged sedation precludes clinical testing.[15]

Evoked potentials (EPs) monitor the integrity of discrete sensory pathways and are thus able to assess components of the brainstem. Somatosensory and brainstem EPs demonstrate successive loss of function of various afferent pathways of the brainstem but, because they rely on the integrity of the whole pathway, a lesion affecting any point of that pathway may result in an absent EP and a false-positive result.[16] Like EEG, EPs are susceptible to sedative drugs and metabolic derangement and, in association with their anatomical limitations, this renders them unreliable as sole confirmatory tests of brain death.

DIAGNOSING BRAIN DEATH IN SPECIAL CIRCUMSTANCES

Although there are no published reports of recovery of neurological function after a diagnosis of brain death using standard criteria,[11] there are numerous case reports highlighting situations or conditions that may mimic brain death and thus lead to erroneous conclusions if unrecognised. These invariably involve failure to consider the preconditions and exclusions prior to clinical testing.

SEDATIVE DRUGS AND HYPOTHERMIA

The effects of high-dose sedative infusions may persist for several days after discontinuation, particularly in critically ill patients. During this time the patient fails to satisfy the preconditions for the clinical confirmation of brain death. This is particularly an issue following infusion of barbiturates, which are increasingly being used to treat intractable intracranial hypertension. As with other sedatives, plasma barbiturate levels may not reflect clinical effect, particularly in the context of brain injury, and there is no consensus regarding a minimal plasma concentration at which brain death can be diagnosed. On the other hand, waiting an arbitrary period of time, usually several days, to allow sedative effects to wear off represents an inefficient use of ICU resources and additional pressures for relatives. Although the effects of high-dose barbiturates can mimic brain death, particularly in the presence of hypothermia, this is rare except in children. Therefore, in the presence of other stigmata of brain death, such as dilated unreactive pupils, characteristic cardiovascular changes and diabetes insipidus, the diagnosis is rarely in doubt.

A case of misdiagnosed 'reversible' brain death has been reported in a 55-year-old man who had been treated with therapeutic hypothermia and propofol and fentanyl infusions following cardiopulmonary arrest and serves to highlight the potential pitfalls.[18] Sixteen hours after re-warming the patient satisfied the clinical criteria for brain death and these findings were confirmed 6 hours later. However, cough and gag reflexes, and spontaneous respiration, returned after a further 24 hours, although this recovery was transient and did not affect the ultimate outcome. The potential confounding effects of a very high cumulative dose of fentanyl in the presence of renal and hepatic impairment, and therapeutic hypothermia, were not given sufficient weight in this case, which illustrates the importance of meticulous attention to exclusion of confounding factors prior to proceeding with clinical examination of the brainstem.

Confirmatory tests may have a role when the diagnosis of brain death using clinical criteria is complicated by the effects of prolonged sedation, particularly in the context of hypothermia. The Australian and New Zealand guidance offers the greatest assistance in this regard, permitting brain death to be determined by demonstration of the absence of intracranial blood flow if any of the preconditions for clinical testing, including the presence of residual sedation, are not met.[19]

INABILITY TO COMPLETE THE APNOEA TEST

In patients with high spinal cord injury the possibility that apnoea might be related to the cord injury itself brings some uncertainty to the diagnosis of brain death. The degree of any spinal cord injury must therefore be quantified clinically, structurally and functionally by meticulous clinical examination, magnetic resonance imaging and electrophysiological tests.[20] In other situations, such as after polytrauma, the apnoea test cannot be attempted, or has to be abandoned, because of haemodynamic instability or poor oxygenation. The majority of guidelines consider the apnoea test to be a fundamental component of the clinical determination of brain death, although in Australia and New Zealand brain death can be confirmed by demonstration of the absence of intracranial blood flow if the apnoea test cannot be completed.

OTHER CONDITIONS

Other brain death mimics, including baclofen and valproic acid overdose, snake bite and some neurological conditions, have been reported. Cranial nerve involvement and respiratory paralysis are features of Guillain–Barré syndrome and may cause diagnostic confusion, although pupil dilatation is rare. Brainstem reflexes may also be absent in brainstem encephalitis but the patient is usually drowsy rather than comatose. The preconditions for the diagnosis of brain death are not

met in any of these conditions and meticulous application of the clinical criteria and careful examination will ensure that they cannot be mistaken for brain death.

CHILDREN

Special care is recommended in diagnosing brain death in children younger than 5 years of age.[21] In those over 2 months, the general criteria are the same as for adults but the period of observation should be longer and confirmatory investigations, such as EEG or cerebral angiography, are often conducted. A higher Pa_{CO_2} target is also recommended during the apnoea test. As in adults the tests must be undertaken by two competent clinicians but, in the case of young children, one should be a paediatrician and one not directly involved in the child's care.

Coma may occur for a wide variety of reasons in infants younger than 2 months of age but hypoxic–ischaemic encephalopathy is the most likely cause of devastating brain injury in this age group. Diagnosing brain death can be difficult because it may be impossible to demonstrate structural brain damage and thus the preconditions are rarely met. Associated severe multi-system failure is common at this young age, so it may not be appropriate or necessary to confirm brain death if care can be withdrawn on the grounds of futility.

Apnoea and coma are common in preterm infants (gestational age less than 37 weeks) but the development of brainstem reflexes is variable and therefore their absence difficult to demonstrate. In the UK it has been suggested that the concept of brain death is inappropriate in this age group and decisions to withdraw support should be made on the basis of futility.

SUMMARY

More than 40 years since the concept was first introduced, practice guidelines to determine brain death are available in many countries but there is large international variation in their content and application. There is thus a need for an international consensus on the determination of brain death; this should retain clinical tests at its core and clarify the role of, and indications for, confirmatory investigations. Flexibility should be maintained and, as in other areas of medicine, the clinical findings should be interpreted with common sense by an experienced and humane physician.

Meningitis and encephalomyelitis

Angus M Kennedy

Infections of the cranial contents can be divided into those that affect the meninges (meningitis) and those that affect the brain parenchyma (encephalitis). Chronic, insidious or rare infections are beyond the scope of this chapter, which will focus on acute bacterial and viral causes of meningitis and encephalomyelitis. The crucial questions to be considered for an individual patient with a neurological infection are to determine why this individual, in this place, has developed this disease, at this time.[1]

Definitions

- *Meningitis:* infection or inflammation of the meninges and subarachnoid space. The infection can be caused by viruses, bacteria, fungi or protozoa. Meningeal inflammation may be caused by subarachnoid haemorrhage, vaccination or be a manifestation of other multi-organ diseases such as systemic lupus erythematosus, sarcoidosis, lymphoma or meningeal micro-metastases from a disseminated carcinoma.
- *Aseptic meningitis:* a generic term for cases of meningitis in which bacteria cannot be isolated from the cerebrospinal fluid. The differential diagnosis includes: (1) viral meningitis, (2) partially treated bacterial meningitis, (3) TB meningitis, (4) fungal meningitis, (5) lymphoma, (6) sarcoidosis, and (7) other collagen vascular diseases. The most common causes of aseptic meningitis are viral infection most often due to an enterovirus or coxsackie infection.
- *Encephalitis:* an infection of the brain parenchyma. The patient may have a history of focal symptoms including preceding seizures together with cognitive or behavioural symptoms.
- *Tuberculous meningitis:* causes subacute lymphocytic meningitis. Patients may have a non-specific prodromal phase, including symptoms such as headache, vomiting and fever.
- *Subdural empyema:* a suppurative process in the space between the pia and dura maters.
- *Brain abscess:* a collection of pus within the brain tissue.

BACTERIAL MENINGITIS

Bacterial meningitis is an inflammatory response to infection of the lepto meninges and subarachnoid space. This is characterised by the clinical syndrome of fever, headache, neck stiffness and cerebrospinal fluid pleocytosis. Despite antibiotic therapy some patients continue to suffer significant morbidity and mortality.

The bacterial organisms are usually not confined to the brain and meninges and frequently cause systemic illness – for example, severe sepsis, shock, acute respiratory distress syndrome, and bleeding disorders such as disseminated intravascular coagulation.[2,3]

A variety of other pathogens cause meningeal inflammation, resulting in very similar clinical presentations. Bacterial infections must be treated urgently and appropriately to limit ongoing central nervous system damage. It is also important to treat the complications of meningitis such as seizures and raised intracranial pressure (ICP).

Where possible, spinal fluid examination following a lumbar puncture is required in order to confirm the diagnosis and establish the pathogenic organism responsible. A cerebrospinal fluid (CSF) examination may be contraindicated if there are signs of raised intracranial pressure including:

- papilloedema
- focal neurological signs
- seizures.

These features raise the possibility of an undiagnosed cerebral mass lesion, which, in turn, could cause cerebral herniation should lumbar puncture be performed. A computed tomography (CT) brain scan is required prior to CSF examination in order to rule out this possibility and lessen, but not obviate, the risk of cerebral herniation. Even if the CT brain scan is normal, intracranial pressure may be raised. The importance of performing a safe CSF examination must be balanced against the need to commence immediate treatment in each individual patient.[4,5]

AETIOLOGY

All three main causes of meningitis (see below) are spread by droplet infection or exchange of saliva. Meningitis may occur when pathogenic organisms colonise the nasopharynx and reach the blood–brain barrier. It can also occur as a consequence of infection

in the middle ear, sinus or teeth leading to secondary meningeal infection. Most bacteria obtain entry into the central nervous system via the haematogenous route. As the organisms multiply, exponentially, they release cell wall products and lipopolysaccharide, which can generate a local inflammatory reaction that itself also releases inflammatory mediators. The net result of the release of cytokines, tumour necrosis factor and other factors is associated with a significant inflammatory response. Vasculitis of central nervous system (CNS) vessels, thrombosis, cell damage and exudative material all contribute to vasogenic and cytotoxic oedema, altered blood flow and cerebral perfusion pressure. Later on, infarction and raised intracranial pressure occur.[6]

The inflammatory events seen with infection are summarised in **Figure 54.1**.

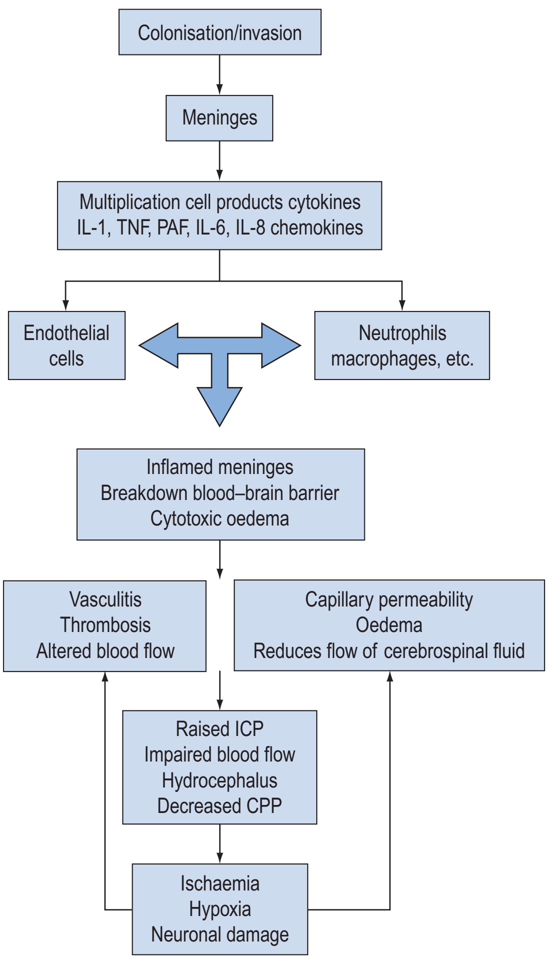

Figure 54.1 Cascade of events in meningitis. IL=interleukin; TNF=tumour necrosis factor; PAF=platelet-activating factor; ICP=intracranial pressure; CPP=cerebral perfusion pressure.

ORGANISMS

Acute bacterial meningitis can be caused by many species of bacteria, although three organisms are commonly reported, including:

- *Haemophilus influenzae*
- *Streptococcus pneumoniae*
- *Neisseria meningitidis* (which account for 70% of cases in the neonatal period).

Until the advent of the meningitis vaccination programme *H. influenzae* type B was the most common cause of bacterial meningitis. Recently *S. pneumoniae* and *N. meningitidis* were considered the main causes, although one study suggested that *Listeria monocytogenes* is the second most common isolate in the adult population. The emergence of pneumococcal strains that are resistant to penicillin has also influenced the epidemiology of meningitis.[7]

NOSOCOMIAL INFECTIONS

Common systemic nosocomial pathogens such as *Escherichia coli*, *Pseudomonas* spp., *Klebsiella* and *Acinetobacter* spp. account for a high percentage of nosocomial infections of the meninges.

IMMUNOCOMPROMISED HOSTS

In the immunocompromised patient with meningitis (e.g. human immunodeficiency virus, HIV), fungal, viral and cryptococcal meningitis should be considered.[8]

NEUROSURGERY AND TRAUMA

Infections following skull trauma are frequently caused by *Staphylococcus aureus* and *Staphylococcus epidermis*, which should be considered in those with shunts or other intracranial devices.

CLINICAL PRESENTATION

The history may reveal evidence of trauma or infection. Meningitis usually presents with an acute onset of:

- fever
- headache
- neck stiffness
- photophobia
- altered conscious level
- irritability
- seizures (paediatric).

However, in the immunocompromised, elderly or infant patient, non-specific features such as a low-grade fever or mild behavioural change may be all that is apparent. Many of the classic symptoms are late manifestations of meningitis and are preceeded by early symptoms such as leg pain or cold hands, which may not immediately suggest the more serious underlying diagnosis.

If the presenting symptoms are highly suggestive of pyogenic bacterial meningitis, empirical administration

Table 54.1 Cerebrospinal fluid changes in meningitis

	NORMAL	BACTERIAL	VIRAL
Appearance	Clear	Turbid/purulent	Clear/turbid
White cell count	<5 per mm^3 mononuclear	200–10 000 per mm^3 predominantly polymorphonuclear	<500 per mm^3 mainly lymphocytes
Protein	0.2–0.4 g/L	0.5–2.0 g/L	0.4–0.8 g/L
Glucose	Blood glucose	≤Blood glucose	Blood glucose pressure is usually raised

Table 54.2 Empirical antibiotics for meningitis

INDICATION	ANTIBIOTIC	DOSE
<50 years	Ceftriaxone *or* cefotaxime	2–4 g q. 24 h, 2 g q. 4 h
>50 years or impaired cell immunity	Ceftriaxone *or* cefotaxime Cefotaxime+ampicillin *or* penicillin G	2–4 g q. 24 h, 2 g q. 4 h 2 g q. 4 h or 3–4 MU q. 4 h
Drug-resistant *Streptococcus pneumoniae*	Ceftriaxone+rifampicin *or* vancomycin	2–4 g q. 8 h, 2 g q. 4 h 0.5 g q. 6 h
Neurosurgery shunts trauma	Ceftazidime+nafcillin *or* vancomycin+aminoglycoside (gentamicin 5–7 mg/kg stat)	2 g q. 8 h, 2 g q.4 h 0.5 g q. 6 h 2 mg/kg q. 8 h

of a third-generation cephalosporin such as cefotaxime or ceftriaxone should be given.

It is important to identify from the history any reports of preceding trauma, upper respiratory tract infection or ear infection. Symptoms may develop over hours or days. Specific infections relate partly to an individual's age.

Neurological signs can be present with meningitis, but signs such as nuchal rigidity, stiffness and a positive Kernig's sign (pain and hamstring spasm resulting from attempts to straighten, e.g. with the hip flexed) are not always present, and a number of studies have shown that the classic triad of signs were present in less than 50% of cases. There may be focal neurological signs. Systemic signs may occur most often in meningococcal disease where a haemorrhagic, petechial or purpuric rash may be observed. Digital gangrene or skin necrosis may occur. Some patients present severely septic with acute respiratory distress syndrome and disseminated intravascular coagulation.

Approximately 25% of patients have a seizure during the course of the illness. Differential diagnosis may include subarachnoid haemorrhage, migraine, encephalitis and tumour.

INVESTIGATIONS

The patient with suspected bacterial meningitis requires immediate blood cultures and should be given empirical i.v. antibiotics if there is likely to be any delay in further assessment (**Table 54.1**).

CSF FINDINGS

A CSF examination is a vitally important investigation that will definitively confirm the diagnosis of bacterial meningitis. Its value should, in this regard, not be dismissed. Concern about the risks of coning following lumbar puncture should be considered in the context of patients' symptoms where the presence of coma, seizures, focal neurological signs and papilloedema may suggest raised intracranial pressure. Neuroimaging may not always predict whether it is safe to lumbar puncture a patient, although it may provide some level of reassurance that it is safe to proceed. A young patient who is alert, orientated, immune competent and without focal signs can safely have a lumbar puncture without prior imaging.

Bacterial meningitis is suggested when there is:

- polymorphic leucocytosis
- low CSF glucose relative to the plasma value
- raised CSF protein concentration.

An urgent Gram stain and microbiological culture are mandatory. The Gram stain is positive in approximately 50–60% of cases. A CSF examination shortly after empirical antibiotics may, but does not necessarily, decrease the diagnostic sensitivity of CSF culture. Polymerase chain reaction (PCR) techniques can now be used to detect the presence of different organisms. A throat swab should be routinely taken. The clinical decision-making process to determine whether a patient does or does not have bacterial meningitis cannot be modelled easily and is reliant on both clinical and

laboratory findings as well as observation of the patient over time.

As spread is haematogenous, blood cultures comprise an important investigation in meningitis, and a number of sets of cultures should be sent. It is advisable to routinely check a full blood count clotting profile (to exclude DIC) and biochemistry including blood glucose level. A chest X-ray and blood gases should be performed to identify systemic involvement. Obviously, relevant areas such as infected sinuses or ears should be examined if there is any indication that they are implicated.

MANAGEMENT

Broad-spectrum antibiotics should be started as early as possible and continued until bacterial identification is made (**Table 54.2**). Antibiotic selection is influenced by the clinical situation in conjunction with known allergies or local patterns of antibiotic resistance and the CSF findings. Delay in administering antibiotics is a significant risk factor for a poor prognosis. In the abscence of a known organism, empirical choice for antibiotics has been complicated by the development of resistance. Penicillin G, ampicillin and third-generation cephalosporins are typical first-line agents. Until recently, ampicillin was appropriate for pneumococcal, meningococcal and listerial infections but the emergence of resistant strains significantly influences local antibiotic practice and hence choice. If there is a history of recent head injury, a broad-spectrum cephalosporin may be indicated with vancomycin. Discussions with local microbiology services are recommended. If the CSF examination identifies the organism then specific regimens can be prescribed (**Table 54.3**).

It is more difficult to select an appropriate empirical antibiotic in the immunocompromised patient. When the organism has been identified and sensitivity results are available, it will probably be necessary either to change or to rationalise the antibiotics being given.[9]

In all cases, it is important to monitor the clinical response and antibiotics should be reviewed and appropriately altered once antibiotic sensitivities are known, or if a patient is not improving. A repeat CSF examination should be performed if there is concern about antibiotic sensitivity or selection. In those with penicillin-resistant pneumococcal meningitis, a CSF examination 48 hours after presentation is recommended to ensure bacteriological improvement. Antibiotics should be given for 10–14 days, although a shorter course may be adequate in some circumstances. Intrathecal antibiotics are not recommended.

STEROID ADMINISTRATION

The benefit of steroid administration in adult meningitis has been debated, but clear guidance is now available to support its routine use as the Cochrane Database of 1800 adults and children demonstrated a reduction in mortality, hearing loss and and neurological complications. Concerns still remain, however, that dexamethasone may adversely effect CSF penetration or cause longer-term cognitive problems.[10] An extended and more established literature exists for the use of steroids in bacterial meningitis in children and these studies confirm a benefit for those with *H. influenzae* type B infection with a reduction in the frequency of post-meningitis deafness.

RECOMMENDATIONS IN ADULTS

Dexamethasone is an adjuvant treatment and should be given with the first dose of antibiotics and continued 6-hourly for 4 days (0.6 mg/kg daily).

ANTICONVULSANTS

Focal or generalised seizures should be treated immediately with i.v. benzodiazepines to stop the seizures and the individual then subsequently loaded with i.v.

Table 54.3 General recommendation for known organisms

ORGANISM	ANTIBIOTIC	SECOND LINE OR ALLERGY
Streptococcus pneumoniae (penicillin-resistant)	Ceftriaxone+vancomycin *or* rifampicin	Vancomycin+rifampicin
Streptococcus pneumoniae (penicillin-sensitive)	Penicillin G	Ceftriaxone *or* chloramphenicol
β-Haemolytic *Streptococcus*	Penicillin *or* ampicillin	Cefotaxime *or* chloramphenicol *or* vancomycin
Haemophilus influenzae	Ceftriaxone *or* cefotaxime	Chloramphenicol
Neisseria meningitidis	Penicillin G	Ceftriaxone *or* chloramphenicol
Listeria monocytogenes	Ampicillin+gentamicin	Trimethoprim+sulfamethoxazole
Enterobacteriaceae	Ceftriaxone+gentamicin	Quinolones
Pseudomonas aeruginosa	Ceftazidime+tobramycin	Quinolones

Always check local sensitivity as resistance patterns are variable.

phenytoin or levetiracetam. The possibility of the following should be considered:

- raised intracranial pressure
- cerebritis
- cerebral abscess
- septic venous thrombosis.

The development of seizures may be indicative of a poor prognosis.

INTRACRANIAL PRESSURE

Intracranial hypertension is a common complication of meningitis. Intracranial pressure monitoring may be required and standard measures such as hyperventilation, mannitol infusion or CSF drainage may be considered. Depending upon the particular circumstance, serial lumbar punctures or external ventricular drainage should be implemented.

GENERAL MANAGEMENT CONSIDERATIONS[11]

Intravenous fluid therapy

Normal haemodynamics should be maintained. Currently, there is emphasis on maintaining the cerebral perfusion pressure at around 70 mmHg (9.33 kPa). Inappropriate antidiuretic hormone secretion may occur in meningitis.

Respiratory

It is important to secure the airway and respiratory support may be required for those with severe shock or profound coma. Attention should be paid to management of the unconscious patient with appropriate mouth and eye care. Physiotherapy will be required in order to prevent the onset of pressure sores. Surgical evaluation may be needed for skin necrosis.[12,13]

Public health

Meningitis prophylaxis is recommended for close (kissing contacts) associates and for those medical personnel with close contact. A 2-day course of oral rifampicin 600 mg 12-hourly is recommended. There should be procedures in place for alerting the infectious disease team and public health.

PROGNOSIS

Untreated bacterial meningitis is usually fatal. Appropriate therapy significantly reduces the mortality rate, but recent studies still show that the overall mortality is approximately 18%. Mortality is slightly higher in those who have seizures, when there have been delays introducing treatment, and if the patient is either elderly or very young[13,14] (see Table 54.3).

CRYPTOCOCCAL MENINGITIS

Cryptococcus neoformans is a yeast that can cause a chronic meningitis that is clinically similar to *tuberculous meningitis*. It is most frequently found in those who are immunocompromised, such as with HIV infection. The CSF should be stained with India ink and appropriate antifungal chemotherapy instituted (amphotericin B). Management of the raised intracranial pressure may necessitate daily lumbar punctures or CSF diversion.

VIRAL MENINGITIS

The majority of cases of viral meningitis are benign, usually self-limiting conditions that are often caused by enterovirus or coxsackie infection. Some are caused by arboviruses. The same viruses that produce meningitis can also cause encephalitis. Herpes simplex virus type 1 usually produces encephalitis but rarely causes meningitis. Other viruses causing CNS infections include echoviruses, mumps, polio and HIV. Patients with migrainous headaches often receive a lumbar puncture to rule out viral meningitis, which paradoxically may prolong their hospital stay with a post-lumbar-puncture headache and migraine.

CLINICAL PRESENTATION

Patients usually present with symptoms of meningeal irritation, fever, headache, neck stiffness, retrobulbar pain, photophobia, vertigo, nausea and vomiting that are less severe than those with bacterial meningitis. The presence of intellectual impairment, focal neurological symptoms or seizures suggests that the brain parenchyma is involved often due to meningo-encephalitis. A detailed travel history should be obtained as this may alter the differential diagnosis in terms of the likely organism. True viral meningitis develops over hours to days but rarely lasts longer than 7–10 days. A variety of associated symptoms, such as nausea, vomiting and generalised malaise, may accompany this condition.[15]

INVESTIGATIONS

A CSF examination is important and usually shows:

- a mild to moderate lymphocytic pleocytosis
- a mildly elevated CSF protein concentration
- normal glucose concentration.

Staining for microorganisms, including bacteria, mycobacterium tuberculosis and cryptococcal meningitis, is necessary. Sites for culture include the mucous membranes, throat, skin and rectum.

MANAGEMENT

Acute viral meningitis is usually a self-limiting condition and only supportive therapy is required with analgesia and bedrest. Viral meningitis caused by herpes simplex virus (HSV) 1 or 2 may require i.v. aciclovir. Acute HIV infection causing meningitis may respond to retroviral therapy.

ENCEPHALITIS

Encephalitis is a viral infection of the brain but can be due to either direct infection or by post-infectious, immune-mediated mechanisms. HSV-1, the most common and serious cause of focal encephalitis, usually affects the temporal and frontal lobes. There are a large number of arboviruses that cause epidemics of encephalitis. Encephalitis acts as a sentinel for new and emerging infections, including Japanese encephalitis, Nipah virus, Hendra virus, a variety of bat-associated viruses as well as West Nile and some tick-borne encephalitides such as Murray Valley encephalitis.

West Nile virus is now the most common cause of epidemic viral encephalitis in some countries. Although, on neuroimaging, changes in the basal ganglia may suggest the diagnosis, a CSF pleocytosis may be a more obvious diagnostic finding. Specific CSF antibodies can be sent for West Nile virus. There are also a variety of antibody-mediated encephalitides that target synaptic proteins. These include myeloid cell nuclear differentiation antigen (MNDA) receptor antibodies and voltage-gated K^+ channel antibodies.[16]

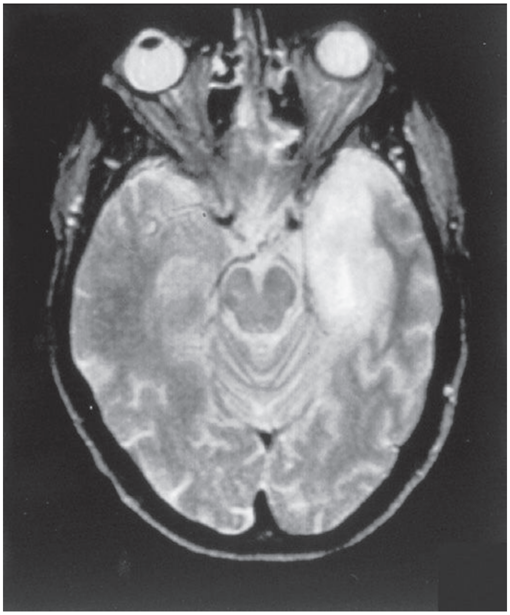

Figure 54.2 Enhanced temporal lobe with herpes simplex encephalitis.

CLINICAL PRESENTATION

The key clinical pointer to encephalitis is the presence of focal neurological symptoms indicating involvement of the brain parenchyma. In particular, the presence of speech disturbance, seizures, altered cognition and disturbance of conscious level suggest this.

Diagnosis can be difficult.

- Abnormalities on cranial imaging such as T2-weighted magnetic resonance imaging (MRI) may support this diagnosis (**Fig. 54.2**).
- Electroencephalogram (EEG) studies may show slow-wave activity or epileptiform discharges in temporal lobe.
- PCR examination of the CSF examination may confirm the virus at a later date.

A systematic approach to the investigation of those with encephalitis has been proposed and national guidelines developed in order to reduce the proportion of unidentified cases.[17]

TREATMENT

Understanding, and if at all possible identifying, the specific aetiological cause of an individual's encephalitis may ultimately have the greatest influence on the successful management of individual patients.[18]

Specific treatment for HSV encephalitis requires i.v. aciclovir at a dose of 30 mg/kg per day for 14 days. If untreated, the mortality of HSV encephalitis is approximately 70% but there is still a 25% mortality in patients treated with optimal therapy, and patients can be left with significant disability in terms of cognitive dysfunction or seizures. Most patients with significant cerebral oedema receive empirical steroids, although there are no clinical trials to support this therapy. Aciclovir can cause renal impairment and the patient should be hydrated intravenously and renal function monitored.[19] Aggressive treatment of seizures is important.

Cytomegalovirus (CMV) infection requires antiviral therapy with ganciclovir or valganciclovir. CMV may cause a ganglionitis and polyradiculitis, which may suggest this diagnosis clinically in an immunocompromised patient.

Most CNS viruses cause neuronal damage but chronic Jakob–Creuzfeldt (JC) virus infection in oligodendrocyes causes the syndrome of progressive multifocal leucoencephalopathy (PML). This condition presents with a subacute onset of confusion, weakness and visual symptoms, usually in an immunosuppressed individual. The MRI scan is usually suggestive but CSF examination with PCR amplification of the JC virus particles may be required. Currently, no specific therapy for PML exists. The survival of HIV patients with associated PML is poor, averaging 6 months in 90% of individuals.

Viral infection with HIV-1, measles and rubella can also cause chronic CNS infection leading to chronic encephalitides. *Mycoplasma* infection can give rise to post-infectious encephalitis.

A number of systemic neurological conditions (e.g. lymphoma, Lyme disease, sarcoidosis and vasculitides such as Behçet disease) may present with aseptic meningitis. It is therefore important to consider these

systemic conditions in those presenting with viral meningitis or encephalitis.

TUBERCULOUS MENINGITIS

Tuberculous meningitis has a variable natural history with a range of different clinical presentations. This and the lack of specific and sensitive tests hinder the diagnosis of this condition. Approximately 10% of individuals with tuberculosis develop meningeal involvement. A variety of risk factors such as HIV, diabetes mellitus and the recent use of steroid use may increase the risk of tuberculous meningitis.[20]

CLINICAL FEATURES

Tuberculous meningitis has a very varied clinical presentation. Often, it is heralded by a non-specific prodromal phase, frequently but not necessarily including headache, vomiting and fever. Of one case series that included those admitted to an intensive care unit, only 65% had fever, 52% had focal neurology and 88% had signs of meningism. A variety of cranial nerve palsies can occur, but other presentations include those seen with stroke, hydrocephalus and tuberculoma.

DIAGNOSIS

An investigation of the differential diagnosis of tuberculous meningitis is important. PCR amplification of mycobacterial DNA, which in the case of TB meningitis has not been fully evaluated, usually requires a lumbar puncture examination. Those who are immunosuppressed may have an atypical CSF appearance, but this may include normal CSF examinations in occasional HIV individuals. Tuberculosis culture from CSF is required but may take up to 6 weeks before a positive culture result is available. Imaging studies may show a basal meningitis and hydrocephalus but these features are non-specific.[21]

Current advice suggests that the first 2 months of treatment should comprise quadruple therapy:

- Isoniazid oral/i.v. 10 mg/kg per day up to 300 mg; it is bactericidal and has good CNS penetration
- Pyrazinamide oral/i.v. 25 mg/kg per day up to 2.5 g/day
- Rifampicin high dosage as poor penetration, 10 mg/kg per day up to 600 mg
- Ethambutol i.v. high dosage as it is highly protein bound and therefore has poor penetration.

Streptomycin is used rarely. The toxicity of the agents must be monitored in terms of renal and liver function and the effect on other organs such as the eye.

There is increasing multidrug-resistant tuberculous meningitis, especially in the HIV-positive population, and so sensitivity is important. Some clinical trials suggest that steroids have a beneficial effect in some groups of patients.[22] Patients may require neurosurgical intervention for the treatment of hydrocephalus.

SUBDURAL EMPYEMA

This is a collection of pus between the dural and arachnoid space and usually is a consequence of middle ear or sinus disease. It may follow cranial osteomyelitis related to previous neurosurgery. Head trauma can also be responsible.

Individuals present acutely with headache, fever, neck stiffness, seizures and focal neurological symptoms. Meningeal signs and evidence of hemispheric dysfunction with sinusitis should suggest the diagnosis.

DIAGNOSIS

CT and MRI are both effective in demonstrating a fluid collection.

Surgical intervention, drainage and appropriate antibiotic regimens are required. Both Gram-positive, *Staphylococcus* and *Streptococcus*, and Gram-negative organisms may be implicated. Initial broad-spectrum cover should be narrowed to targeted treatment when the organism or organisms are known.

PROGNOSIS

This condition if left untreated is invariably fatal. With treatment, mortality is in the order of 20% but neurological sequelae are common.

EPIDURAL INFECTION

Cranial and spinal epidural abscess is an infection between skull and dura often as a consequence of osteomyelitis, from an orbital infection or malignancy. There is an occasional incidence following an epidural. It is similar to subdural empyema. The organism involved where a catheter or drain is implicated is often the same as that found at the skin; hence *S. aureus* is frequently responsible.

PRESENTATION

Inflammation is commonly, but not always, present on the back, and is usually generalised to the area of the back involved. There may be local tenderness over the site associated with redness of the catheter insertion site. Fever is common. Initially mild neurological deficit may rapidly progress leading to para/quadriparesis.

Blood cultures may be positive and may indicate the organism.

DIAGNOSIS

CT and MRI are both effective in diagnosis.

Spinal decompression and drainage are urgently required. This is usually a nosocomial infection and therefore resistant organisms are commonly found. Antibiotics should be specific for the organisms involved and may need to be continued for prolonged periods, often weeks, to eradicate the infection.

Where there have been neurological symptoms and signs prior to surgery, residual deficit is common. In one series, the recovery rate for patients with paresis/plegia after lumbar epidural abscess was 50%, whereas no patients with paresis/plegia following a thoracic abscess recovered. The majority of long-term survivors had severe neurological deficits.

CEREBRAL VENOUS AND SAGITTAL SINUS THROMBOSIS

Venous and sinus thrombosis may occur in the context of infection; in particular meningitis, and epidural or subdural abscess. It may also be secondary to facial or dental infection. It may have no septic aetiology but can occur either as an isolated event or in association with prothrombotic problems such as diabetic ketoacidosis, MDMA (ecstasy) abuse, oral contraceptives and hereditary prothrombotic conditions in pregnancy.[23]

Clinical signs at presentation include:

- headache
- focal neurological deficits in particular cranial nerves
- seizures
- papilloedema.

The diagnostic sensitivity of CT, MRI and digital subtract angiography are 59%, 86% and 100%, respectively, but MRI with magnetic resonance angiography reaches 96% (**Fig. 54.3**).

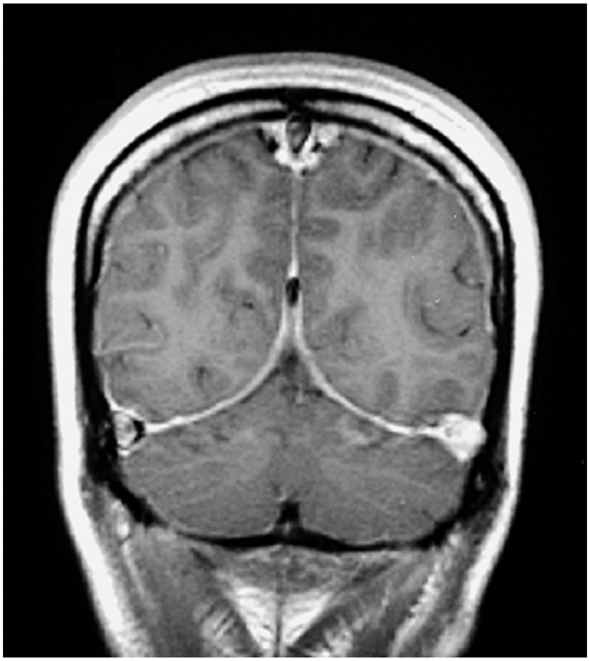

Figure 54.3 Magnetic resonance imaging (MRI) of superior sagittal sinus thrombosis: coronal T1-weighted post-contrast MRI; patient developed a sinus thrombosis following protracted labour and delivery.

TREATMENT

- Treat the primary infection if present.
- Anticoagulants are the mainstay of treatment. Paradoxically there are often areas of intracerebral haemorrhage in patients with sinus thrombosis. The presence of such haemorrhages is not a contraindication to anticoagulation.

BRAIN ABSCESS

AETIOLOGY

Direct spread from bone or dura or may be via haematogenous spread. Predisposition includes cranial trauma, neurosurgery, chronic ear or sinus disease, suppurative lung disease, congenital heart disease and recurrent sepsis. Immunological compromise may predispose to more exotic organisms, but more common organisms include *Staphylococcus* spp. associated with trauma, and *Streptococcus*, *Bacteroides* and Gram-negative bacteria, which are common with lung disease or recurrent sepsis.

PRESENTATION

Severe headache, vomiting, obtundation, seizures and focal neurological signs. Neck stiffness is often absent. Clinical sepsis may not be obvious.

DIAGNOSIS (**FIG. 54.4**)

- An obvious primary source of infection
- Evidence of raised ICP
- Focal cerebral or cerebellar signs.

INVESTIGATIONS

- Lumbar puncture is potentially dangerous and contraindicated
- CT scan – contrast will usually show a ring-enhancing lesion
- MRI
- Assessment of the patient's immune status
- Specific blood tests such as HIV and toxoplasma serology.

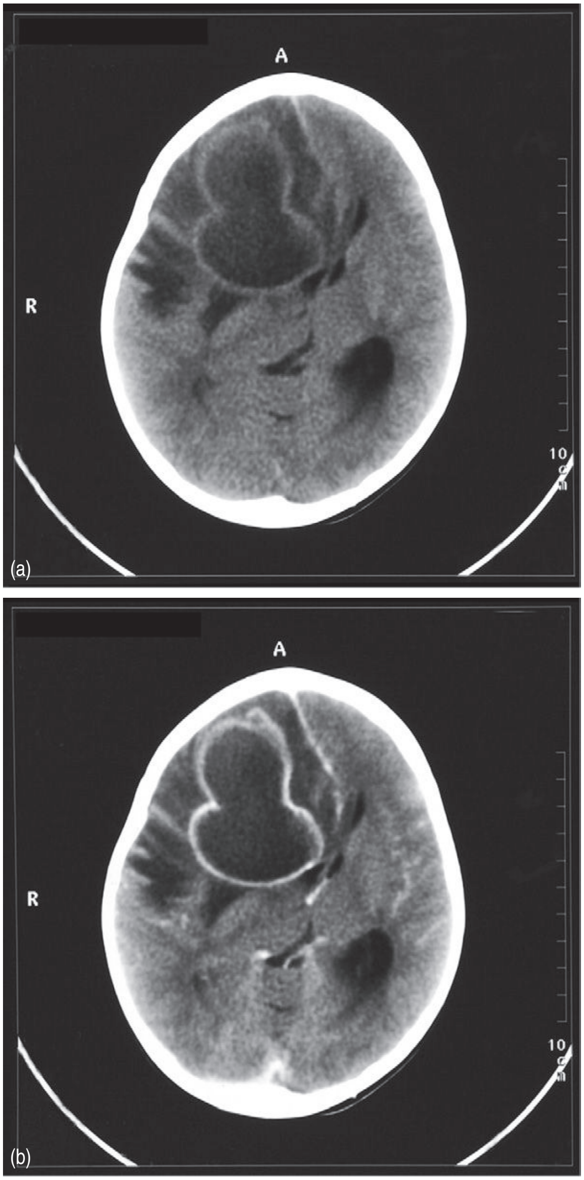

Figure 54.4 Abscess: (a) pre-contrast and (b) post-contrast.

TREATMENT

Indications for surgery include large single lesions, relief of raised ICP and the need for tissue diagnosis.

Antibiotics are the mainstay of therapy. If the organism is known then the treatment should be specific. In the absence of a definitive organism, penicillin plus chloramphenicol (as for meningitis) and metronidazole 500 mg i.v. 8-hourly or 500 mg rectally 12-hourly should be empirical therapy. Administer cefotaxime l–2 g i.v. 6–8-hourly and metronidazole 500 mg i.v. 8-hourly. If there is a recent history of trauma or neurosurgery, then a regimen that will cover *Staphylococcus* should he used. Antibiotics should be continued for 3–6 weeks.

Supportive therapy limits morbidity, which is nevertheless high. Mortality from cerebral abscesses is still 10–20%.[24]

LYME DISEASE

This is a tick-borne multisystem disease with dermatological, cardiological, rheumatological and neurological effects caused by the spirochaete *Borrelia burgdorferi*.

A history of potential exposure should be sought but is not always found. Usually the disease presents as an acute febrile illness with gastrointestinal upset, but it may present in a variable fashion neurologically including as a cranial neuropathy (commonly a facial palsy) or as meningo-encephalitis or radiculopathy. It may also cause lymphocytic meningitis and may have been diagnosed as 'viral' meningitis in the past. A variety of longer-term neurological sequelae have been described.[25]

INVESTIGATIONS

CSF

White cell count is equivocal but may be raised. Protein is normal or marginally raised and sugar is normal or marginally low. Serology and ELISA may be difficult. PCR may be helpful. It may have characteristic MRI appearances. Vaccination is the only empirically demonstrated method to prevent Lyme disease.

TREATMENT

Beta-lactam antibacterials such as penicillin V, amoxicillin and cefuroxime are effective first-line treatment. The optimal duration of treatment is not known, but 10–21 days is recommended.[26,27] Practice parameters for the treatment of nervous system Lyme disease state that nervous system infection responds favourably to penicillin, ceftrixaone, cefotaxime and doxycycline. Prolonged treatment with antibiotic appears to have no benefit in preventing post-Lyme syndrome.

OTHER DISEASES

There are several other diseases that may have an encephalopathic component. Cerebral malaria is dealt with elsewhere. *Legionella* may lead to subclinical or clinical neurological manifestations, ranging from headache to coma or encephalopathy usually seen in conjunction with pneumonia, in addition to possible renal impairment. Similarly, *Mycoplasma* has been associated with an encephalitic picture characterised by impaired consciousness and seizures, and by normal or non-specific neuroradiological findings. Occasionally, symmetrical lesions in the putamen and its external surrounding areas have been seen.

Septic encephalopathy has been described as a common complication in the critically ill, presenting in a panoply of ways, from the agitated confused state seen in acute sepsis through to profound loss of consciousness. The aetiology is almost certainly multifactorial involving changes in cerebral blood flow, alteration in oxygen extraction, cerebral oedema, disruption of the blood–brain barrier, the presence and effects of diverse inflammatory mediators and abnormal neurotransmitter activity. Deranged liver and renal function contribute. It is a syndrome of exclusion based on observation and circumstantial evidence. The EEG is usually abnormal with decreased fast activity and an increase of slow-wave activity, but the findings are not pathognomonic. There are no specific treatments. In general terms, outcome appears to correlate with the management of the underlying sepsis.[28]

Tetanus

Jeffrey Lipman

Tetanus is a preventable, often Third-World disease frequently requiring expensive First-World technology to treat. It is an acute, often fatal disease caused by exotoxins produced by *Clostridium tetani,* and is characterised by generalised muscle rigidity, autonomic instability and sometimes convulsions.

EPIDEMIOLOGY

Recently, tetanus has become a disease of the elderly and debilitated in developed countries, as younger people are likely to have been immunised.[1] In the USA, its incidence decreased from 0.23 per 100 000 in 1955 to 0.04 per 100 000 in 1975, and remained stable thereafter.[1] It is reported that 1 million people annually are afflicted with tetanus signifying a global incidence about 18 per 100 000 population, with an estimated world mortality of about 500 000 per year. [2] It is geographically prevalent in rural areas with poor hygiene and medical services. Thus, tetanus remains a significant public health problem in the developing world, primarily because of poor access to immunisation programmes. In addition, modern management requires ICU facilities, which are rarely available in the most severely afflicted populations.[3] Therefore, tetanus will continue to afflict developing populations in the foreseeable future.

PATHOGENESIS

C. tetani is an obligate anaerobic, spore-bearing, Gram-positive bacillus. Spores exist ubiquitously in soil and in animal and human faeces. After gaining access to devitalised tissue, spores proliferate in the vegetative form, producing the toxins tetanospasmin and tetanolysin. Tetanospasmin is extremely potent; an estimated 240 g could kill the entire world population,[4] with 0.01 mg being lethal for an average man. Tetanolysin is of little clinical importance.

C. tetani is non-invasive. Hence, tetanus occurs only when the spores gain access to tissues to produce vegetative forms. The usual mode of entry is through a puncture wound or laceration, although tetanus may follow surgery, burns, gangrene, chronic ulcers, dog bites, injections such as with drug users, dental infection, abortion and childbirth. Tetanus neonatorum usually follows infection of the umbilical stump. The injury itself may be trivial, and in 20% of cases there is no history or evidence of a wound.[1] Germination of spores occurs in oxygen-poor media (e.g. in necrotic tissue), with foreign bodies, and with infections. *C. tetani* infection remains localised, but the exotoxin tetanospasmin is distributed widely via the bloodstream, taken up into motor nerve endings, and transported into the nervous system. Here, it affects motor neuron end-plates in skeletal muscle (to decrease release of acetylcholine), the spinal cord (with dysfunction of polysynaptic reflexes) and the brain (with seizures, inhibition of cortical activity and autonomic dysfunction). Tetanus is not communicable from person to person.

The symptoms of tetanus appear only after tetanospasmin has diffused from the cell body through the extracellular space, and gained access to the presynaptic terminals of adjacent neurons.[1] Tetanospasmin spreads to all local neurons, but is preferentially bound by inhibitory interneurons – that is, glycinergic terminals in the spinal cord, and γ-aminobutyric acid (GABA) terminals in the brain.[3] Its principal effect is to block these inhibitory pathways. Hence stimuli to and from the central nervous system (CNS) are not 'damped down'.

ACTIVE IMMUNOPROPHYLAXIS

Natural immunity to tetanus does not occur. Tetanus may both relapse and recur. Victims of tetanus must be *actively immunised*. Tetanus toxoid is a cheap and effective vaccine that is thermally stable.[4] It is a non-toxic derivative of the toxin that, nevertheless, elicits and reacts with antitoxic antibody. By consensus, an antibody titre of 0.01 U/mL serum is protective.[5] In a damped-down form, tetanus has been reported in a few victims with much higher serum antibody titres.[1]

In adults, a full immunisation course consists of three toxoid doses, given at an optimal interval of 6–12 weeks between the first and second doses, and 6–12 months between the second and third doses. A single dose will offer no immediate protection in the unimmunised, but a full course should never be repeated. Neonates have immunity from maternal antibodies. Children over 3 months should be actively immunised, and need four doses in total. Two or more doses to child-bearing

females over 14 years will protect any child produced within the next 5 years. Pregnant females who are not immunised should thus be given two spaced-out doses 2 weeks to 2 months before delivery. Booster doses should be given routinely every 10 years.

Side-effects of tetanus toxoid are uncommon and not life-threatening. They are associated with excessive levels of antibody due to indiscriminate use.[6] Common reactions include urticaria, angio-oedema and diffuse, indurated swelling at the site of injection.

CLINICAL PRESENTATION

The incubation period (i.e. time from injury to onset of symptoms) varies from 2 to 60 days. The period of onset (i.e. from first symptom to first spasm) similarly varies. Nearly all cases (90%), however, present within 15 days of infection.[7] The incubation period and the period of onset are of prognostic importance, with shorter times signifying more severe disease.

Presenting symptoms are pain and stiffness. Stiffness gives way to rigidity, and there is difficulty in mouth opening – trismus or lockjaw. Most (75%) non-neonatal generalised tetanus cases present with trismus.[7] Rigidity becomes generalised, and facial muscles produce a characteristic clenched-teeth expression called risus sardonicus. The disease progresses in a descending fashion. Typical spasms, with flexion and adduction of the arms, extension of the legs and opisthotonos, are very painful and may be so intense that fractures and tendon separations occur.[1] Spasms are caused by external stimuli (e.g. noise and pressure). As the disease worsens, even minimal stimuli produce more intense and longer-lasting spasms. Spasms are life-threatening when they involve the larynx and/or diaphragm.

Neonatal tetanus presents most often on day 7 of life,[5] with a short (1-day) history of failure of the infant to feed. The neonate displays typical spasms that can be easily misdiagnosed as convulsions of another aetiology. In addition, because these infants vomit (as a result of the increased intra-abdominal pressure) and are dehydrated (because of their inability to swallow), meningitis and sepsis are often considered first.

Autonomic dysfunction occurs in severe cases,[7–9] and begins a few days after the muscle spasms. (The toxin has further to diffuse to reach the lateral horns of the spinal cord.) There is increased basal sympathetic tone, manifesting as tachycardia and bladder and bowel dysfunction. Also, episodes of marked sympathetic overactivity involving both α- and β-receptors occur. Vascular resistance, central venous pressure and, usually, cardiac output are increased, manifesting clinically as labile hypertension, pyrexia, sweating, and pallor and cyanosis of the digits.[8] These episodes are usually of short duration and may occur without any provocation. They are caused by reduced inhibition of postsynaptic sympathetic fibres in the intermediolateral cell column, as evidenced by very high circulating norepinephrine (noradrenaline) concentrations.[1,9] Other postulated causes of this variable sympathetic overactivity include loss of inhibition of the adrenal medulla with increased epinephrine (adrenaline) secretion, direct inhibition by tetanospasmin of the release of endogenous opiates, and increased release of thyroid hormone.[1,3]

The role of the parasympathetic nervous system is debatable. Episodes of bradycardia, low peripheral vascular resistance, low central venous pressure and profound hypotension are seen, and are frequently preterminal.[8] Sudden and repeated cardiac arrests occur, particularly in intravenous drug abusers.[9] These events have been attributed to total withdrawal of sympathetic tone, since it is unresponsive to atropine.[10] However, they may be caused by catecholamine-induced myocardial damage[9,11] or direct brainstem damage.[9] Whatever the mechanism, patients afflicted with the autonomic dysfunction of tetanus are at risk of sudden death.

Local tetanus is an uncommon mild form of tetanus with a mortality of 1%. The signs and symptoms are confined to a limb or muscle, and may be the result of immunisation. *Cephalic tetanus* is also rare. It results from head and neck injuries, eye infections and otitis media. The cranial nerves, especially the seventh, are frequently involved and the prognosis is poor. This form may progress to a more generalised form. Tetanus in heroin addicts seems to be severe, with a high mortality, but numbers are small.[9,12]

DIAGNOSIS

The diagnosis is clinical and often straightforward. There are no laboratory tests specific to tetanus. *C. tetani* is cultured from the wound in only a third of cases. The most common differential diagnosis is dystonic reaction to tricyclics. Other differential diagnoses include strychnine poisoning, local temporomandibular disease, local oral disease, convulsions, tetany, intracranial infections or haemorrhage and psychiatric disorders.

MANAGEMENT

Initial objectives of treatment are to neutralise circulating toxin (i.e. passive immunisation) and prevent it from entering peripheral nerves (i.e. wound care), as well as eradicating the source of the toxin (i.e. extensive surgery, hygiene, wound care and antibiotics). Treatment then aims to minimise the effect of toxin already bound in the nervous system, and to provide general supportive care.

PASSIVE IMMUNISATION

Human antitetanus immunoglobulin (HIG) has now largely replaced antitetanus serum (ATS) of horse

origin, as it is less antigenic. HIG will at best neutralise only circulating toxin, but does not affect toxins already fixed in the CNS (i.e. it does not ameliorate symptoms already present).

Current recommendations for HIG in tetanus are 500 IU.[2] It has been suggested that unimmunised patients or those whose immunisation status is unknown should be given HIG on presentation with contaminated wounds. No controlled study has shown this to be more effective than wound toilet and penicillin administration.

Intrathecal administration of antitetanus toxin is still controversial[14,15] with the most recent meta-analysis reporting benefit. [16] Moreover, suitable intrathecal preparations are not widely available. Side-effects of human antitetanus toxin include fever, shivering and chest or back pains. Cardiovascular parameters need to be monitored, and the infusion may need to be stopped temporarily if significant tachycardia and hypotension are present.[1,6,13] If HIG is not available, equine ATS can be used after testing and desensitisation.[1]

ERADICATION OF THE ORGANISM

WOUND CARE

Once HIG has been given, the infected site should be thoroughly cleaned and all necrotic tissue extensively debrided.

ANTIBIOTICS

Tetanus spores are destroyed by antibiotics. The vegetative form (bacillus) is sensitive to antibiotics in vitro. However, in vivo efficacy depends on the antibiotic concentration at the wound site, and large doses may be required, Recommended antibiotic regimens include:

- *metronidazole 500 mg IV 8-hourly for 10 days:* the drug has a spectrum of activity against anaerobes, is able to penetrate necrotic tissue, and has been shown to be more effective than penicillin in this situation[17]
- *penicillin G 1–3 Mu IV 6-hourly for 10 days:* penicillin is a GABA antagonist in the CNS,[18] and may aggravate the spasms; nevertheless, it is still often used in this situation
- *erythromycin:* this has been used, but should not be routinely used.

SUPPRESSION OF EFFECTS OF TETANOSPASMIN

CONTROLLING MUSCLE SPASMS

In the early stages of tetanus, the patient is most at risk from laryngeal and other respiratory muscle spasm. Therefore, if muscle spasms are present, the airway should be urgently secured by endotracheal intubation or tracheostomy. If respiratory muscles are affected, mechanical ventilation should be instituted. In severe tetanus, spasms usually preclude effective ventilation, and muscle relaxants may be required. Any muscle relaxant can be used.[19] Heavy sedation alone may prevent muscle spasms and improve autonomic dysfunction (see below).

MANAGEMENT OF AUTONOMIC DYSFUNCTION

Autonomic dysfunction manifests in increased basal sympathetic activity[20] and episodic massive outpourings of catecholamines.[20–22] During these episodes, norepinephrine and epinephrine may be up to 10 times basal levels.[20,21] The clinical picture is variable.[22] Hypertension, tachycardia and sweating do not always occur concurrently.

Traditionally, a combination of alpha- and beta-adrenergic blockers has been used to treat sympathetic overactivity. Phenoxybenzamine, phentolamine, bethanidine and chlorpromazine have been used as α-receptor blockers. Ganglion blockers and nitroprusside have occasionally been used. Propranolol and labetalol have had limited success.[23–25] However, unopposed beta-adrenergic blockade cannot be advised. Deaths from acute congestive cardiac failure have resulted.[23,24] Removal of beta-mediated vasodilatation in limb muscle causes a rise in systemic vascular resistance, and beta-blocked myocardium may not be able to maintain adequate cardiac output. Also, with beta blockade, hypotension follows when sympathetic overactivity abates. Esmolol, a very short-acting beta-adrenergic blocker given IV, has been reported to be useful.[26] However, although sympathetic crises can be controlled by esmolol, catecholamine levels remain raised.[22] This raises concern because excessive catecholamine secretion is associated with myocardial damage.[11]

From the above, it appears more logical to decrease catecholamine output. This can be done with sedatives. Benzodiazepines and morphine are successfully used.[21] Morphine and diazepam act centrally to minimise the effects of tetanospasmin. Morphine probably acts by replacing deficient endogenous opioids.[1] Benzodiazepines increase the affinity and efficacy of GABA.[1] Very large doses of these agents (e.g. diazepam 3400 mg/day[21] and morphine 235 mg/day [27]) may be required, and are well tolerated.

Magnesium has been used as an adjunct to sedation,[21,28] now confirmed by a large trial.[29] Magnesium sulphate infusions to keep serum concentrations between 2.5 and 4.0 mmol/L have decreased systemic vascular resistance and pulse rate, with a small decrease in cardiac output.[21,28] In animal studies, magnesium inhibits release of epinephrine and norepinephrine, and reduces the sensitivity of receptors to these neurotransmitters. Magnesium also has a marked neuromuscular-blocking effect, and may reduce the intensity of muscle spasms. Nevertheless, it could not be shown to decrease

the need for mechanical ventilation.[29] However, magnesium sulphate must be used with sedatives,[21] and calcium supplements may be needed when it is infused. Anecdotally, clonidine, a central α_2-stimulant, has successfully produced sedation with control of autonomic dysfunction.[30] It seems sensible to attempt to make use of the central nervous system effects of an α_2-adrenergic agonist, namely sedation and vasodilatation.[31] Intrathecal baclofen has produced similar beneficial results in a series of cases, but significant respiratory depression occurred in a third.[32] When given intrathecally, baclofen can diminish spasms and spasticity, allowing for a reduction in sedative and paralysis requirements.[33]

SUPPORTIVE TREATMENT

Steps should be taken to prevent contractures, nosocomial pneumonias and deep-vein thrombosis. The patient (including the mother if a neonate is afflicted) must be actively immunised. Where possible, supportive psychotherapy should be offered to both patient and family.

COMPLICATIONS

Muscle spasms disappear after 1–3 weeks, but residual stiffness may persist. Although most survivors recover completely by 6 weeks, cardiovascular complications, including cardiac failure, arrhythmias, pulmonary oedema and hypertensive crises, can be fatal. No obvious cause of death can be found at autopsy in up to 20% of deaths. Other complications include those associated with factors shown in **Box 55.1**.

Box 55.1 Factors contributing to death in tetanus

Hypoxia
Complications of mechanical ventilation
Myoglobinuria and its attendant problems
Sepsis, particularly pneumonia
Fluid and electrolyte problems (including inappropriate antidiuretic hormone secretion)
Deep-vein thrombosis and embolic phenomena
Bed sores
Bony fractures

OUTCOME

Recovery from tetanus is thought to be complete. However, in 25 non-neonatal patients followed for up to 11 years,[35] 15 were reported to have one or more abnormal neurological features such as intellectual or emotional changes, fits and myoclonic jerks, sleep disturbance and decreased libido. Of the 10 apparently normal survivors, 6 had electroencephalogram changes. Some of these symptoms resolved within 2 years.

Mortality figures depend on the availability of intensive care. In neonates, the mortality from African countries with no ICU facilities can be up to 80% of cases, but falls to about 10% when artificial ventilation is used. In the USA, mortality in non-neonates relates directly to age, with rates from 0% in patients under 30 years rising to 50% in those 60 years or older. An average of 10% mortality would seem to be reasonable for most ICUs. However, as this disease is easily and completely preventable, loss of life is unacceptable.

Delirium

Timothy M Alce, Valerie Page and Marcela P Vizcaychipi

Delirium is an acute confusional state common in critically ill patients, particularly those who require ventilation. It is an independent predictor of death and long-term cognitive decline. Prompt identification and treatment of delirium in patients aims to improve patient outcomes reducing morbidity, length of stay in ICU and mortality as well as associated financial costs of intensive care.

DEFINITION

Delirium, as defined by the American Psychiatric Association in the Diagnostic and Statistical Manual of Mental Disorders, 4th edition, text revised (DSM-IV-TR), is a disturbance of consciousness that develops over a short period of time, fluctuates and is associated with perceptual changes such as hallucinations (**Box 56.1**).[1] Consciousness in this context consists of arousal and cognition – awake and aware.

Three clinical subtypes of delirium are recognised: hypoactive, hyperactive and mixed, each distinguishable by psychomotor behaviour and arousal. Hypoactive delirium, which is the most common subtype, is often unrecognised or misdiagnosed as depression or sedation. Patients will appear cooperative and docile but will show signs of inattention and will be unable to organise thoughts. Pure hyperactive delirium, in contrast, is much less common (approximately 5%) but more familiar to the clinician and recognisable. Patients will be obviously agitated and aggressive, being uncooperative and combative. These patients are more likely to have hallucinations. Mixed delirium exists when patients fluctuate between hypoactive and hyperactive subtypes.

Delirium tremens, a state of confusion, agitation and hallucinations specifically relates to delirium following alcohol withdrawal.

HISTORICAL PERSPECTIVE

The first records of delirium are from the 5th century BC by Hippocrates who described delirium in an acutely confused patient using the terms phrenitis (frenzy) and lethargus. Da Medicina, a 1st century BC treatise by Aulus Cornelius Celsus used well into the 15th century as a source of medical wisdom, has the first written entry of delirium to describe the acutely confused state. The word delirium comes from the latin *de* away from + *lira* furrow in a field, hence literally meaning *going away from the ploughed track.* Until relatively recently those ICU patients who were recognised as delirious were described as either having an encephalopathy or ICU psychosis.

ICU INCIDENCE AND RELEVANCE

The highest incidence rates of delirium of all clinical areas in the hospital, including orthopaedic/care of the elderly wards, is the ICU. Delirium can occur in up to 69% of ventilated patients in the UK.[2] Delirium is an independent predictor of mortality.[3] Compared with case-matched critically ill patients without delirium, those with delirium have three times higher 6-month mortality following ICU admission.[3] Delirium is known to be associated with long-term cognitive decline and early dementia and results in a three-fold increase in the risk of discharge to long-term care.[4] Patients with delirium in ICU are nine times more likely to experience some degree of cognitive impairment following discharge compared with non-delirious ICU patients.[3] In specific risk conditions such as Alzheimer disease the development of delirium has been shown to accelerate cognitive decline.

Clearly, delirium has implications for quality of life and independence of patients and their relatives. Patients with delirium have longer ICU and hospital stays. Moreover, there are increased ICU costs (1.4 fold) and increased overall hospital costs (1.3 fold).[5]

PATHOPHYSIOLOGY

The pathophysiology of delirium is ill defined but there are a number of theories regarding the pathological changes in the brain that result in and from delirium. These range from neuroinflammation with TNFα activation of microglia, impaired oxidative metabolism, altered cerebral blood flow, increased blood–brain barrier permeability, thalamic dysfunction and aberrant levels of large neutral amino acids.[6,7]

It is likely that several mechanisms contribute to the development of delirium, which then results in a common pathway of neurotransmitter imbalance and

Box 56.1 DSM-IV-TR definition of delirium

1. Altered consciousness: reduced clarity of awareness of environment with reduced ability to focus, sustain or shift attention
2. Change in cognition: disorientation, memory disturbance, problem-solving impairment, development of perceptual disturbance
3. Rapid onset (hours to days) and tendency to fluctuate during the day
4. Evidence the condition is caused by physiological consequences of a clinical condition or drug withdrawal/ overdose

Box 56.2 Risk factors for developing delirium in intensive care

ICU delirium modifiable risk factors		Non-modifiable risk factors
Infection	Hyponatraemia	Age, especially over 65
Anticholinergic drugs	Hypoxia	Cognitive impairment
Opiates	Hypercarbia	Dementia
Pain	Acidosis	Depression
Immobility	Polypharmacy	Genetic factors
Dehydration or constipation	Sleep disturbance	Institutionalised residence
Sedative drugs	Use of physical restraints	Liver impairment
Sensory impairment (visual/auditory)	Use of bladder catheter	

resultant cholinergic hypoactivity.[8,9] There is then, inevitably, a relative state of dopamine excess, which can also cause deterioration in attention or consciousness. The interlinking role of acetylcholine and dopamine makes it difficult to ascertain which of these imbalances is primarily responsible for delirium.

Other theories relate to the availability of tryptophan, a metabolic precursor of serotonin, which may play a role since both increased and decreased levels of serotonin are seen in delirium. It is also possible that there is a genetic component for developing delirium. Apolipoprotein E4 (ApoE4) genotype, rather than ApoE2 or ApoE3, is a susceptibility factor for Alzheimer disease possibly by being less able to suppress cerebral inflammation than the other isoforms. In all of these mechanisms of the cause of delirium, the data are conflicting.[10,11]

RISK FACTORS

The numerous risk factors for delirium fall in to two main categories: predisposing (non-modifiable) and precipitating (both modifiable and non-modifiable) (**Box 56.2**). It is important to realise that the risk of delirium increases with the number of risk factors to which the patient is exposed,[12] and a frail, elderly patient with many predisposing factors may develop delirium from only a minor precipitating factor.

The PRE-DELIRIC model described by van den Boogaard et al[13] has been developed to help predict the likelihood that a patient admitted to ICU will develop delirium based on risk factors. It uses various parameters readily available during the first 24 hours of admission – for example, the Acute Physiology and Chronic Health Evaluation score (APACHE-II), metabolic acidosis, urea concentration, use of sedatives, etc. Using this model, the risk factors that confer the highest risk of developing delirium in ICU are coma (from any cause), sedatives and infection.

DIAGNOSIS/SCREENING

Diagnosis of delirium is challenging and difficult. In one study nurses detected daily delirium in only 34.8% of cases, with doctors detecting delirium in only 28%.[14] The key feature to detecting delirium is evidence of inattention. Delirious patients can appear to have normal mental status as they are often able to obey direct commands and will nod randomly to questions.

There are several delirium screening tools available to the clinician to assist in diagnosis of delirium, but few of them have been validated for use in ICU with intubated patients. The most widely used in critical care are the Confusion Assessment Model for ICU (CAM-ICU)[12] (**Fig. 56.1**) and the Intensive Care Delirium Screening Checklist (ICDSC).[15] These tools are designed for clinical use and have been validated for intubated patients. They are non-verbal, simple to use and require minimal training. CAM-ICU is a point-in-time assessment, whereas ICDSC uses information gathered over a nursing shift. These screening tools aim to detect the key features of delirium, which are inattention, disorganised thinking, altered level of arousal with or without hallucinations and altered sleep pattern in the case of ICDSC. Specificity and sensitivity for each of these tools in critically ill patients are 81% and 96% respectively (CAM-ICU)[16] and 99% and 66% respectively (ICDSC).[15] However, a cautionary note was sounded by van Eijk et al. who discovered in a multicentre trial that routine, daily use of CAM-ICU by nursing staff has a specificity of 98% but a sensitivity of only 47%.[17]

MANAGEMENT OF DELIRIUM

GENERAL MANAGEMENT

Initial management should aim at correcting the cause of delirium. If a medical condition has been the trigger or has caused delirium, it is likely that the patient will continue to be delirious, with all the associated neuroinflammation, neurotransmitter imbalance and alterations in cerebral blood flow, until the medical condition has successfully been treated. Reversal of the underlying cause is important and necessary examination and

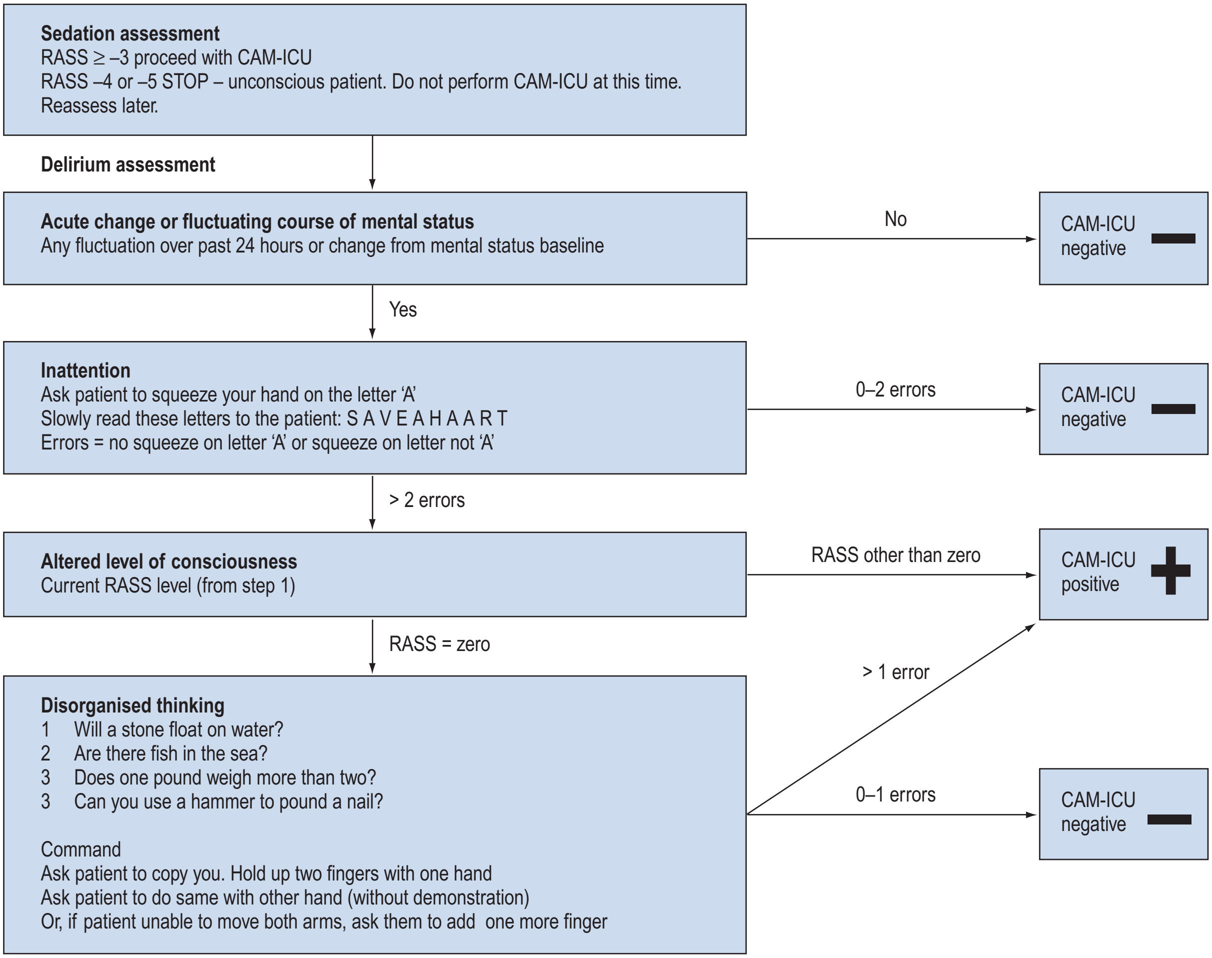

Figure 56.1 Confusion assessment method for ICU (CAM-ICU) flow chart. *(Reproduced with permission from E Wesley Ely, MD MPH.)*

investigations should be undertaken, bearing in mind that there may be more than one precipitating cause.

There are several simple and easy non-pharmacological measures, free from adverse effects, that can be usefully employed with the aim of preventing delirium or reducing its severity.[18] These include clear and firm communication with frequent verbal orientation clues, such as date, time and location. Involvement of relatives assists in giving the patient a sense of familiarity, security and control, and can give the clinician information about the patient's normal mental status before illness. Other environmental factors include keeping noise to a minimum, correcting sensory impairment with hearing aids or spectacles, if worn, and avoiding sleep disturbance by careful timing of treatments and interventions, and by promoting a normal sleep–wake cycle.

Other measures such as correcting electrolytes, restoring oxygenation, controlling febrile episodes, maintaining blood pressure within patient's normal range and treating constipation may be sufficient to treat delirium. Physical restraints, rarely used in the UK, are known to increase the risk of delirium. They should be avoided. Medical restraints, including urinary catheters, ECG leads within other monitoring tools, which will also impact the mobility of patients, should be removed as early as is prudent.

Pain control in critical care is important. Although opioids can be deliriogenic, higher doses of opiates are associated with a significantly lower risk of delirium in intensive care burns patients.[19] It is a difficult balancing act to weigh the risk of opioids precipitating delirium against suffering and possible delirium caused by pain.

Sedation plays a large role in delirium in ICU. All sedative drugs including propofol and fentanyl are likely to precipitate delirium. It is essential to have a sedation protocol with routine sedation scoring, sedation targets and daily sedation holds where appropriate.[20] How the sedatives are used, the type of sedative, the dose and patient susceptibility are all

important considerations. Daily wake-ups combined with spontaneous breathing trials, as the patient clinical condition allows, have been shown to decrease mortality.[21] Deep sedation (i.e. RASS -3 (Richmond Agitation Sedation Scale)) in the first 48 hours of sedation and ventilation on intensive care has been associated with increased time to extubation and mortality.[22] Unless there is a clinical reason to keep a patient sedated (e.g. severe asthma) it is suggested that a daily sedation target of RASS 0 to –1 is appropriate.

It is also good practice to stop any unnecessary drugs, in particular benzodiazepines, steroids and drugs with anticholinergic activity including furosemide and digoxin. Early mobilisation of critically ill patients has been demonstrated to decrease delirium and improves outcomes.[23]

Clinical trials have attempted to address the question whether antipsychotics can be used in prevention of delirium.[24,25] Although these have shown positive effects on delirium, reducing either severity or duration, this has not been translated to an improvement in outcome. Thus, there is currently insufficient robust scientific evidence to recommend the use of prophylactic antipsychotics.

PHARMACOLOGICAL MANAGEMENT

Pharmacological treatment primarily involves the use of dopamine antagonists – typical and atypical antipsychotics.

HALOPERIDOL

Haloperidol is a butyrophenone with partial selectivity for dopamine D2 receptors. Its licensing is variable in different countries (i.v. haloperidol is not licensed in the US) but it is commonly used in critically ill patients, in the UK, where enteral absorption may be impaired and close monitoring is available.

Side-effects include sedation, autonomic effects and, more importantly, extrapyramidal symptoms (e.g. excessive salivation, dystonia). Akathisia, an unpleasant sensation of restlessness, may be confused for continuing agitation. Haloperidol should not be given to patients with Parkinson disease or with a family history of dystonia.

More serious side-effects are neuroleptic malignant syndrome and torsades de pointes, both potentially life threatening. Electrocardiogram (ECG) monitoring to check for QTc prolongation, which increases the risk of torsades, should be carried out prior to starting haloperidol and daily while the patient is receiving the drug. Haloperidol can be used cautiously with a QTc greater than 450 ms (or use an alternative drug) but should not be used at all if the QTc is over 500 ms.

Doses of haloperidol used clinically range from 0.5 mg to 10 mg, although 2.5–5 mg is more common. Maximum dose in 24 hours is 18 mg.

OLANZAPINE, QUETIAPINE, RISPERIDONE

Other antipsychotics have lower incidence of extrapyramidal side-effects. Olanzapine can be given both i.v. and intramuscularly. It is as effective as haloperidol in critically ill patients[25] and is a useful alternative if haloperidol is contraindicated.[26] The starting dose is usually 5 mg, up to 20 mg daily (10 mg in renal failure). For patients with dementia who are agitated, quetiapine and risperidone are recommended. Quetiapine has been shown to decrease delirium in a placebo-controlled trial[27] and risperidone was seen to be as effective as olanzapine in managing delirium.[28]

CLONIDINE, DEXMEDETOMIDINE

Alpha-2 agonists have a sedative effect without GABAergic activity, potentially reducing the requirements of sedation, which itself can be deliriogenic.

Clonidine is favoured by some clinicians if a patient is requiring large doses of sedatives due to agitation. A starting dose would be 1 μg/kg enterally or diluted with saline and given slowly intravenously. Dexmedetomidine, a more highly selective alpha-2 agonist but significantly more expensive, has recently been licensed for use in the UK as a sedative infusion. It may be beneficial in terms of length of time at targeted level of sedation, and less agitated delirium.[29]

ANTICHOLINESTERASES

The use of anticholinesterases, including rivastigmine, for treatment of delirium in critically ill patients is not recommended and may be harmful.[30]

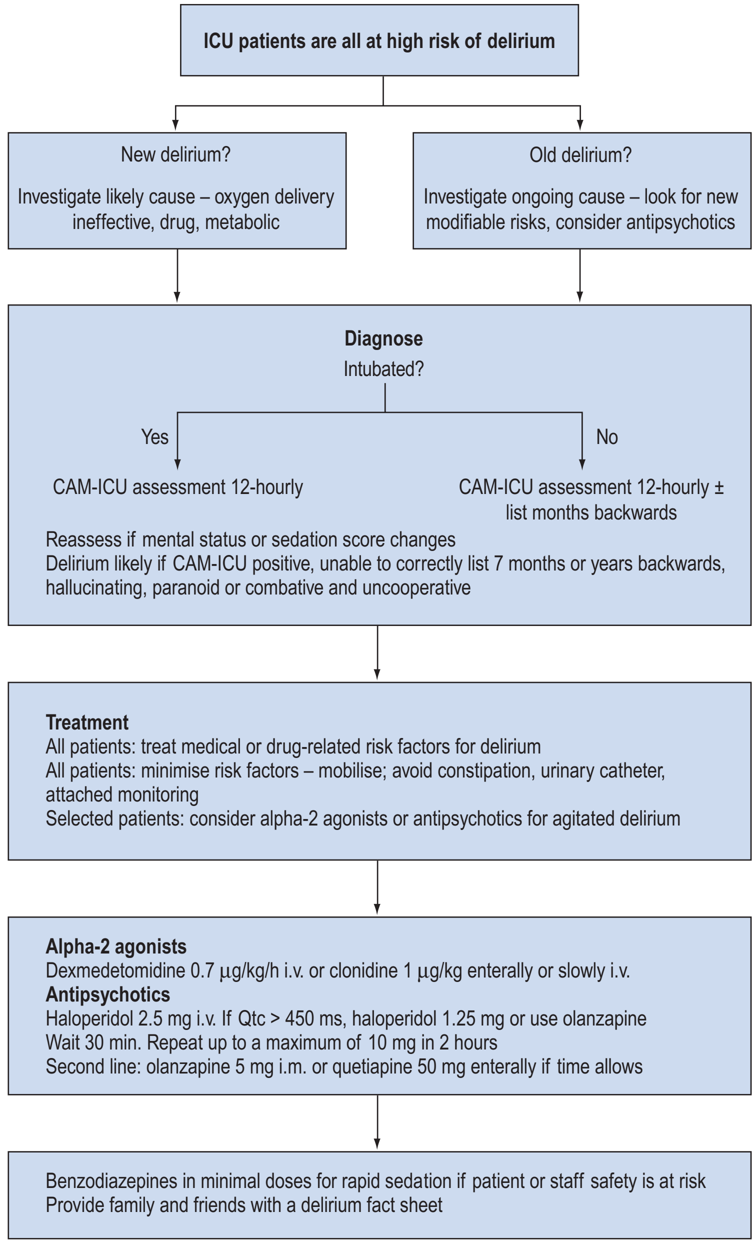
BENZODIAZEPINES

Benzodiazepines should be used only for the treatment of delirium tremens resulting from alcohol withdrawal. A Cochrane review of benzodiazepines in delirium treatment concluded that their use is not indicated in non-alcohol-withdrawal agitated delirium.[31] Indeed, a study in critically ill burns patients revealed benzodiazepine exposure to be an independent risk factor with these patients approximately seven times more likely to develop delirium.[19] However, if agitation is severe and is putting the patient at risk, a *stat* dose of a benzodiazepine might be indicated for rapid control of the incident. Up to 2 mg i.v. of lorazepam every 4 hours may be of benefit. It has rapid onset, short duration of action and low risk of accumulation. Use a lower dose when administering to elderly patients and those with hepatic disease.

SUBSYNDROMAL DELIRIUM

Some patients will not present or progress to full-blown delirium but do have altered mental status. For instance, patients may be able to attend to a conversation while obviously hallucinating. Subsyndromal delirium can be

Figure 56.2 Critical care unit guideline for treatment of delirium.



diagnosed using the ICDSC and it has been associated with worse outcomes, although better than those in patients who demonstrate the full clinical syndrome.

PERSISTENT DELIRIUM

Elderly care patients may be left with persistent delirium, lasting beyond 3 months. The use of antipsychotics may be considered in individual cases, although generally care-of-the-elderly physicians avoid antipsychotics in their practice, relying on non-pharmacological interventions.

A possible ICU management protocol is outlined in **Figure 56.2**.

REMEMBER THE RELATIVES

ICU admission is already a distressing time for relatives and friends of patients and this is exacerbated by their witnessing the delirious patient. It is important to make the relatives aware that mental status changes in ICU are common and inform them that, although delirium can lead to cognitive impairment, generally any acute psychosis is transient. It is often useful to provide a

delirium information leaflet for relatives and reassure them that clinicians are looking for and addressing any treatable cause. Furthermore, it is important to continue to support the patient after recovery. This may involve them talking about their experience, in particular any hallucinations endured during the delirious episode.

SUMMARY

Delirium is commonly encountered in ICU, particularly in intubated patients. Regular assessment of sedation and cognitive function will identify delirious patients early, facilitating prompt management. Delirium primarily requires correction of likely causes (medical or drug related) and minimising known risks (mobilising, avoiding constipation, etc.). First-line treatment of agitated delirium consists of antipsychotics, usually i.v. haloperidol provided QTc is <500 ms. Olanzapine or quetiapine are useful second-line treatments. Avoid benzodiazepines and anticholinergics. Keep friends and relatives, and, whenever possible, the patient informed.

Neuromuscular diseases in intensive care

George Skowronski and Manoj K Saxena

A number of disorders producing generalised neuromuscular weakness can require admission to the ICU, or complicate the course of ICU patients. These may involve:

- spinal anterior horn cells: motor neuron (or neurone) disease, poliomyelitis
- peripheral nerve conduction: Guillain–Barré syndrome (GBS) and related disorders
- the neuromuscular junction: myasthenia gravis, botulism
- muscle contraction: myopathies, periodic paralysis
- mixed disorders: intensive care acquired weakness.

Box 57.1 lists a differential diagnosis of muscle weakness in critically ill patients.

GUILLAIN–BARRÉ SYNDROME AND RELATED DISORDERS

In 1834 James Wardrop reported a case of ascending sensory loss and weakness in a 35-year-old man, leading to almost complete quadriparesis over 10 days, and complete recovery over several months.[1] In 1859, Landry described an acute ascending paralysis occurring in 10 patients, 2 of whom died. Guillain, Barré and Strohl in 1916[2] reported two cases of motor weakness, paraesthesiae and muscle tenderness in association with increased protein in the cerebrospinal fluid – lumbar puncture for cerebrospinal fluid (CSF) examination was first described only in the 1890s.

The many variants of this syndrome and the lack of specific diagnostic criteria have previously resulted in confusion in nomenclature. More recently clinical, electrical and laboratory criteria for the predominant variant – acute inflammatory demyelinating polyradiculopathy (AIDP) – are well described,[3] though 10–15% of cases do not fit these criteria. GBS is best regarded as a heterogeneous group of immunologically mediated disorders of peripheral nerve function.

INCIDENCE

Since the incidence of poliomyelitis has markedly declined due to mass immunisation programmes, GBS has become the major cause of rapid-onset flaccid paralysis in previously healthy people, with an incidence of approximately 1.7 per 100 000.[4] Epidemics have occurred in large populations exposed to viral illness or immunisation but immunosuppression and concurrent autoimmune disease may also be predisposing factors.[5–7] The disorder is commoner in males, and up to 4 times commoner in the elderly. No consistent seasonal or racial predilection has been demonstrated.[4]

AETIOLOGY

Most recent evidence supports the proposition that GBS is caused by immunologically mediated nerve injury.[8] Cell-mediated immunity, in particular, probably plays a significant role, and inflammatory cell infiltrates are often seen in association with demyelination, which is generally regarded as the primary pathological process. Antibodies to a number of nervous system components have been demonstrated in GBS patients, with most interest in recent years focusing on anti-ganglioside antibodies.

The precise mechanism of sensitisation is not known, but clinical associations suggest that antecedent infections or immunisations are commonly involved and two-thirds of cases are preceded by symptoms suggestive of respiratory or gastrointestinal infection. Infective agents implicated include influenza A, parainfluenza, varicella-zoster, Epstein–Barr, chickenpox, mumps, human immunodeficiency virus (HIV),[9] measles virus and *Mycoplasma*. *Campylobacter jejuni* gastroenteritis now appears to be the most common predisposing infection and may be associated with a more severe clinical course; 26–41% of GBS patients show evidence of recent *C. jejuni* infection.[10] Cytomegalovirus infection accounts for a further 10–22% of cases.[11] Immunisations against viral infections, tuberculosis, tetanus[12] and typhoid have all been reported to be associated with the onset of GBS, but most of these reports are anecdotal and of questionable aetiological significance; 65% of patients present within a few weeks of minor respiratory (43%) or gastrointestinal (21%) illness. Surveillance data following the 2009 H1N1 influenza epidemic suggested that the risk of GBS following immunisation was only slightly increased over baseline.[13]

Box 57.1 Differential diagnosis of muscle weakness in critically ill patients

Brainstem
Lower pontine hemorrhage or infarction (locked-in state)
Spinal cord
Transverse myelitis
Compression by tumour, abscess, or haemorrhage
Carcinomatous or lymphomatous meningitis
Peripheral nerve
Intensive care unit acquired neuropathy/neuromyopathy
Phrenic nerve injury during thoracic surgery
Guillain–Barré syndrome
Ingested toxins, including arsenic, thallium, cyanide
Neuromuscular junction
Delayed reversal of neuromuscular blockade
Myasthenia gravis
Lambert–Eaton syndrome
Botulism
Pesticide poisoning
Skeletal muscle
Acute necrotising myopathy
Steroid myopathy
Severe hypokalaemia, hypophosphataemia, and/or hypomagnesaemia
Acute alcoholic myopathy
Polymyositis or dermatomyositis
Toxic myopathy (colchicine, lovastatin, cocaine, bumetanide, amiodarone and others)
Intensive care unit acquired myopathy/neuromyopathy

PATHOGENESIS[8]

The peripheral nerves of patients who have died of GBS show infiltration of the endoneurium by mononuclear cells, in a predominantly perivenular distribution. The inflammatory process may be distributed throughout the length of the nerves, but with more marked focal changes in the nerve roots, spinal nerves and major plexuses. Electron micrographs show macrophages actively stripping myelin from the bodies of Schwann cells and axons. In some cases, Wallerian degeneration of axons is also seen, and failure of regeneration in these cases may correspond with a poor clinical outcome.

The underlying immune response is complex and poorly understood, but serum from GBS patients produces myelin damage in vitro when complement is present.[14] Although antibodies to various glycolipids have been demonstrated in GBS, these are generally in low titre and can occasionally be seen in controls. Patients with recent *C. jejuni* infection have a high incidence of antibodies to the ganglioside GM1.[10] Antibodies to GD1a and GQ1b gangliosides are associated with the rarer AMAN and AMSAN variants (see below).[15] The basis of the effectiveness of plasma exchange and immunoglobulin therapy is likely to be blocking of demyelinating antibodies by several mechanisms.[16]

CLINICAL PRESENTATION

The majority of patients describe a minor illness in the 8 weeks prior to presentation, with a peak incidence 2 weeks beforehand. Approximately half the patients initially experience paraesthesiae, typically beginning in the hands and feet. One-quarter complain of motor weakness, and the remainder have both.[8] Motor weakness proceeds to flaccid paralysis, which becomes the predominant complaint. Objective loss of power and reduction or loss of tendon reflexes usually commence distally and ascend, but a more haphazard spread may occur. Cranial nerves are involved in 45% of cases, most commonly the facial nerve, followed by the glossopharyngeal and vagus nerves. One-third of patients require ventilatory support.

In the Miller–Fisher syndrome, a variant of GBS,[17] cranial nerve abnormalities predominate, with ataxia, areflexia and ophthalmoplegia as the main features. This is strongly associated with recent *C. jejuni* infection and with the presence of GQ1b antibodies.

Another subgroup of patients presents with a primarily axonal neuropathy – acute motor–sensory axonal neuropathy (AMSAN). In these cases motor and sensory axons appear to be the primary targets of immune attack, rather than myelin. These patients have a more fulminant and severe course, and there is again a strong association with *C. jejuni* infection.[18]

In typical GBS, sensory loss is generally mild, with paraesthesiae or loss of vibration and proprioception, but occasionally sensory loss, pain or hyperaesthesia can be prominent features. Autonomic dysfunction is common, and a major contributor to morbidity and mortality in ventilator-dependent cases.[19] Orthostatic or persistent hypotension, paroxysmal hypertension and bradycardia are all described, as are fatal ventricular tachyarrhythmias. Sinus tachycardia is seen in 30% of cases. Paralytic ileus, urinary retention and abnormalities of sweating are also commonly seen.

DIFFERENTIAL DIAGNOSIS

Most of the important alternative diagnoses are listed in **Box 57.2**. In patients with prolonged illness, the possibility of chronic inflammatory demyelinating polyradiculopathy (CIDP) should be considered.[20] In this condition, preceding viral infection is uncommon, the onset is more insidious and the course is one of slow worsening or stepwise relapses. Corticosteroids and plasma exchange are possibly effective in this disorder, but adequate studies of immunosuppressive drugs have not been carried out.

An intermediate *subacute* polyradiculopathy (SIDP) as well as a recurrent form of GBS are also described, and all of these variants may be part of the spectrum of a single condition. However, a purely motor axonal neuropathy (acute motor–axonal neuropathy, AMAN), which causes seasonal childhood epidemics mimicking classical GBS in China and elsewhere,[21] appears to be a distinct entity. Once again, this is strongly associated with *C. jejuni* infection.

Box 57.2 Diagnostic criteria for typical Guillain–Barré syndrome[3]

Features required for diagnosis
Progressive weakness in both arms and both legs
Areflexia
Features strongly supportive of the diagnosis
Progression over days to 4 weeks
Relative symmetry of symptoms
Mild sensory symptoms or signs
Cranial nerve involvement, especially bilateral weakness of facial muscles
Recovery beginning 2–4 weeks after progression ceases
Autonomic dysfunction
Absence of fever at onset
High concentration of protein in cerebrospinal fluid protein, with fewer than 10×10^6 cells/L
Typical electrodiagnostic features
Features excluding diagnosis
Diagnosis of botulism, myasthenia, poliomyelitis or toxic neuropathy
Abnormal porphyrin metabolism
Recent diphtheria
History or evidence of lead intoxication
Purely sensory syndrome, without weakness

INVESTIGATIONS

In over 90% of patients, CSF protein is increased (greater than 0.4 g/L), within 2 weeks of onset of symptoms. The level does not correlate with the clinical findings. A pleocytosis with lymphocytes and monocytes in the CSF may be seen in a small proportion of patients, especially later in the disease. Nerve conduction studies typically demonstrate reduced conduction velocity and prolonged distal latencies,[22] but there is no consensus on precise electrophysiological criteria for the various subtypes.[22] Severely reduced distal motor amplitude and a predominantly axonal pattern are associated with more severe disease and a guarded prognosis.

MANAGEMENT

Although the management of the patient with severe and protracted GBS provides a major challenge, the prognosis is generally good if complications can be treated early or avoided.

SPECIFIC THERAPY

Plasma exchange (plasmapheresis) is of value in GBS and in two trials a reduction in patients requiring mechanical ventilation, reduced duration of mechanical ventilation for those who required it, reduced time to motor recovery and time to walking without assistance were demonstrated.[23,24] Mortality, however, was not altered. Plasma exchange was most effective when carried out within 7 days of onset of symptoms. The currently recommended plasma exchange schedules consist of four exchanges of 1–2 plasma volumes each, over 1–2 weeks.[25] Adverse events are common, and some relate to the disease itself.[26] Fresh frozen plasma is reported to have more side-effects than albumin as the replacement fluid.[26]

Immunoglobulin therapy was as effective as plasmapheresis[27] and previous concerns of higher recurrence rates are probably unfounded. Because of its ease of use, many authorities now advocate immunoglobulin as the treatment of choice.[28] A dose of 2 g/kg body weight intravenously, over 2–5 days, is the current recommendation.[29]

About 10% of patients relapse after initial treatment with either plasmapheresis or immunoglobulin; most respond well to a further course. There appears to be no benefit in combining plasmapheresis and immunoglobulin treatments, or in crossing over from one to the other.[30]

A Cochrane review confirms that low- or high-dose corticosteroids are of no value,[31] and may even slow recovery. The combination of high-dose steroids with immunoglobulin does not affect the long-term outcome.[32]

SUPPORTIVE CARE

RESPIRATORY

In the spontaneously breathing patient, chest physiotherapy and careful monitoring of respiratory function are of paramount importance. Regular measurement of vital capacity is probably the best way to predict respiratory failure, and is more reliable than arterial blood gases.[33] The latter nevertheless remain a useful guide. Any patient with a vital capacity less than 15 mL/kg or 30% of the predicted level, or a rising arterial P_{CO_2} is likely to require mechanical ventilation.

Bulbar involvement should be carefully sought, as there is a significant risk of aspiration of upper airway secretions, gastric contents or ingested food. The cough reflex may be inadequate, and airway protection by tracheal intubation or tracheostomy is then required. Oral feeding should be stopped in any patient in whom bulbar involvement is suspected.

Mechanical ventilation is mandatory if coughing is inadequate, pulmonary collapse or consolidation develop, arterial blood gases are significantly abnormal, vital capacity is less than predicted tidal volume (approximately 10 mL/kg), or the patient is dyspnoeic, tachypnoeic or appears exhausted. Mechanical ventilation, if necessary, will probably be required for several weeks (although there is wide variation), and early tracheostomy should be considered.

CARDIOVASCULAR

Cardiac rhythm and blood pressure should be monitored. Sinus tachycardia is the commonest autonomic manifestation of GBS and usually requires no active treatment. Induction of anaesthesia appears particularly likely to induce serious arrhythmias. Use of suxamethonium may contribute significantly to this[34] and, as with many other neuromuscular disorders, should be avoided. Endotracheal suctioning has also been associated with serious arrhythmias. Cardiovascular

instability may also be exacerbated by a number of other drugs (**Box 57.3**). These, likewise, should be avoided or used with great care.

Mild hypotension and bradycardia may require no treatment, particularly if renal and cerebral functions are maintained. However, blood volume expansion or inotropic drugs may be required in some cases. Hypertension is often transient, but occasionally requires appropriate drug therapy. Hypoxia, hypercarbia, pain and visceral distension should be excluded as causes.

FLUIDS, ELECTROLYTES AND NUTRITION

Paralytic ileus is not uncommon, especially immediately following the institution of mechanical ventilation, and a period of parenteral nutrition may be required. However, wherever possible, nasoenteric feeding should be instituted because of its significantly greater safety. Energy and fluid requirements are considerably reduced in these patients.

SEDATION AND ANALGESIA

In non-ventilated patients, sedation should be avoided because of the potential for worsening respiratory and upper airway function. In ventilated patients, sedation becomes less necessary as the patient becomes accustomed to the ventilator, but night sedation may help to preserve diurnal rhythms. Limb pain, particularly with passive movement, is very common and often quite severe. Quinine, minor and non-steroidal analgesics and antidepressant drugs may all be tried, but the pain can be difficult to control and opioids are often required. Methadone, transdermal fentanyl, gabapentin and tramadol have all been advocated.

GENERAL AND NURSING CARE

A comprehensive programme of physiotherapy should be implemented by nurses and physiotherapists, with careful attention to pressure area care, the maintenance of joint mobility and pulmonary function. Nosocomial infection should be actively sought with culture of urine and respiratory secretions at least twice weekly. Sites of vascular access should be inspected frequently, and changed whenever necessary. It may be possible to manage stable long-term patients without venous access. Care should be taken to prevent corneal ulceration and faecal impaction.

Prophylaxis against venous thromboembolism should be given, and enterally administered low-dose warfarin may be preferable to twice-daily heparin injections in long-stay patients. Psychological problems, especially depression, are common, and some patients are helped by antidepressant drugs. Good communication and rapport between the patient and staff, involvement of allied health practitioners, the provision of television, radio and reading aids and, where possible, occasional trips out of the ICU are all of great value.

Box 57.3 Drugs associated with cardiovascular instability in Guillain–Barré syndrome[94]

Exaggerated hypotensive response
Phentolamine
Nitroglycerin
Edrophonium
Thiopentone
Morphine
Furosemide
Exaggerated hypertensive response
Phenylephrine
Ephedrine
Dopamine
Isoprenaline
Arrhythmias
Suxamethonium
Cardiac arrest
General anaesthesia

Modified from Dalos et al,[94] with permission.

PROGNOSIS

The nadir of the disease is reached within 2–4 weeks, and gradual resolution follows over weeks to months. Of those who survive the acute illness, 70% are fully recovered within 1 year, and a further 20% are left with only minor limitation. Poor prognostic features[35] include age over 60 years, rapid progression to quadriparesis in less than 7 days, the need for mechanical ventilation (except for children),[36] and a preceding diarrhoeal illness.[37] Even in patients ventilated for more than 2 months, gradual improvement may continue for 18 months to 2 years.[38] These severely affected patients require a protracted period of rehabilitation.

Death in up to 25% of GBS patients has been reported in those requiring intensive care.[39] Many of these deaths were due to potentially avoidable problems such as respiratory arrest, ventilator malfunction and intercurrent sepsis, and considerably better results have been achieved.[23] A more representative estimate of the overall mortality is 5–8%.[35]

WEAKNESS SYNDROMES COMPLICATING CRITICAL ILLNESS

A number of neuromuscular disorders specifically associated with critical illness have been described over the last 30 years. They are probably much more common than previously appreciated and may occur in up to 46% (95% CI 43–49%) of patients who require prolonged mechanical ventilation, have sepsis, or multiorgan failure.[42] These disorders include neuropathies, myopathies and combinations of both. Variations in nomenclature, the lack of a pragmatic, simple diagnostic test, and confusion with other disorders, such as GBS and corticosteroid-induced myopathy, have further complicated this area. There is also considerable overlap among the various subtypes. Sepsis, neuromuscular-

blocking agents (NMBA), disuse atrophy, asthma, corticosteroids and the multiple organ dysfunction syndrome (MODS) have all been implicated.

Intensive care unit acquired weakness (ICUAW) is now the preferred term used to encompass this broad group of heterogeneous disorders and is potentially classifiable (based on electrophysiology and tissue biopsy) into the subcategories of critical illness neuropathy, myopathy and neuromyopathy.[43] The diagnosis of ICUAW requires the clinical context of an acute process of high illness severity often requiring prolonged organ support, and is usually associated with a period of protracted immobilisation. Key clinical signs that support a diagnosis of ICUAW include the presence of normal cognition and consciousness, sparing of the cranial nerves, and the presence of symmetrical flaccid weakness. A common feature of ICUAW is the involvement of the respiratory musculature, which results in rapid shallow breathing with reduced clearance of respiratory secretions.

Although two subgroups of ICUAW are outlined below, a number of rarer variants have also been described.

CRITICAL ILLNESS POLYNEUROPATHY

This acute, diffuse, mainly motor neuropathy is probably the commonest of these disorders. It usually presents in the recovery phase of a severe systemic illness with persistent quadriparetic weakness, hyporeflexia and difficulty in weaning from respiratory support. There appears to be a specific association with severe sepsis and MODS. Histological and electrophysiological features are consistent with axonal degeneration. The mortality in this group is high, presumably reflecting that of the underlying condition.

CRITICAL ILLNESS MYOPATHY

This disorder is linked with asthma and with the use of corticosteroids, NMBA and, less convincingly, aminoglycosides and beta-adrenergic agonists. Reflexes are preserved except in severe cases, as is sensation. Elevated blood CPK concentrations are often seen. A few patients have a more severe, fulminant form with very high CPK levels, frank rhabdomyolysis and, rarely, renal failure. Electrophysiological findings are somewhat variable, though muscle necrosis is usually apparent on histology. Although steroidal muscle relaxants (pancuronium or vecuronium)[44] have been particularly implicated, the disorder has also been seen with other types of NMBA.

DIFFERENTIAL DIAGNOSIS (**BOX 57.4**)

The influence of drugs (particularly anxiolytics and analgesics), metabolic abnormalities (electrolyte abnormalities, altered renal and hepatic function) and hypothermia should always be excluded when unexplained neuromuscular weakness appears in an intensive care patient. The possibility of a coincident illness such as the Eaton–Lambert syndrome, myasthenia gravis, vasculitis or GBS must also be carefully considered. Severe catabolism and disuse atrophy are common in many of these patients and can themselves result in significant weakness.

MANAGEMENT

No specific therapies are available, but minimisation of corticosteroids, sedatives and NMBA, with the aim of maintaining an awake, communicative patient, may be beneficial. Patient evaluation ideally should include daily grading of muscle strength. In a cooperative patient this may be performed using the Medical Research Council (MRC) score, which grades strength from 0 to 5 in three functional muscle groups in each limb. This gives a sum score that ranges from 0 (paralysis) to 60 (full strength), with ICUAW defined as a score of less than 48.[43,45]

Ancillary investigations (nerve conduction, electromyogram and tissue biopsy) assist with the classification of ICUAW, but remain primarily research tools because of technical difficulties and the lack of a specific therapeutic intervention.

PROGNOSIS

The prognosis is generally good providing the underlying acute and chronic disorders can be addressed. The influence of these factors is reflected in the variable extent and duration of recovery (from a few weeks to several months, with some symptoms and signs persisting long term). ICUAW has been associated with prolonged weaning from mechanical ventilation, increased duration of intensive care and hospital stay.[46] Long-term associations include increased physical disability and increased mortality,[47] but it remains difficult to

Box 57.4 Clinical features suggesting intensive care unit acquired weakness

- Onset of weakness is after the acute presentation
- Clinical context includes acute, severe illness requiring either prolonged mechanical ventilation, or sepsis and multi-organ support
- Exclude direct effects of sedation or neuromuscular blockade
- Normal cognition presence of flaccid, symmetrical motor weakness (with muscle wasting) affecting limbs and respiratory muscles, but sparing cranial nerves
- Reflexes are absent if a primarily neuropathic pathology, or reduced/absent if primarily a myopathic pathology. Sensation may be affected with primarily neuropathic lesions
- Muscle strength grade (using Medical Research Council sum score – see text) <48/60

distinguish whether these associations are modifiable by intervention or whether they are simply a consequence of the underlying illness.

MYASTHENIA GRAVIS

MG is an autoimmune disorder caused by antibodies directed against acetylcholine (ACh) receptors in skeletal muscle. Despite its relative rarity, it is the most studied and best understood clinical disorder of neuroreceptor function, and arguably the best understood organ-specific autoimmune disease. It is characterised clinically by weakness or exaggerated fatigability on sustained effort. Intensive care is most commonly required because of severe involvement of the bulbar or respiratory muscles, which may be the result of a spontaneous exacerbation of the disease, a complication of drug therapy, intercurrent illness or surgery, or following surgical thymectomy – a definitive treatment for some patients.

INCIDENCE

The incidence of MG is approximately 1 in 20 000 in the USA. There is no racial or geographic predilection. Although MG can occur at any age, it is very rare in the first 2 years of life, and the peak incidence is in young adult females. Overall, females are affected about twice as often as males. This gender predilection decreases with increasing age, and there is a smaller, second incidence peak in elderly males.[48]

AETIOLOGY AND PATHOPHYSIOLOGY

In 75% of cases, there is histological evidence of thymic abnormality. Thymic hyperplasia is present in the majority of patients, but approximately 10% have a thymoma. The latter appears more common in the older age group. The precise role of the thymus is uncertain, but ACh receptors are present in the myoid cells of the normal thymus, and there is evidence that anti-ACh receptor antibody production is mediated by both B and T lymphocytes of thymic origin. Other organ-specific autoimmune disorders, most commonly thyroid disease[49] but also rheumatoid arthritis, lupus erythematosus and pernicious anaemia, are significantly associated with MG, and autoantibodies to other organs may be seen in MG patients without evidence of disease.

Children born to mothers with MG demonstrate transient weakness (‘neonatal MG’) in about 15% of cases. A number of congenital myasthenic syndromes exist, in which symptoms develop in infancy, without evidence of autoantibody production.[50] A familial tendency is more common in this group, and structural changes at the neuromuscular junction have been demonstrated.

The stimulus to autoantibody production is not known, but these can be detected in about 90% of patients with generalised myastheni a. They may interfere with neuromuscular transmission by competitively blocking receptor sites, by initiating immune-mediated destruction of receptors, or by binding to portions of the receptor molecule that are not part of the ACh receptor site but nevertheless are important in allowing ACh to bind.

CLINICAL PRESENTATION

Ptosis and diplopia are the most common initial symptoms and in 20% of cases the disorder remains confined to the eye muscles (ocular MG).[51] Bulbar muscle weakness is common and may result in nasal regurgitation, dysarthria and dysphagia. Limb and trunk weakness can occur with varying distribution, and is usually asymmetrical. Some patients complain of fatigue rather than weakness, and may be misdiagnosed as having psychiatric problems. However, weakness can be elicited by sustained effort of an involved muscle group (e.g. sustained upward gaze is often worse at the end of the day and improves with rest).

INVESTIGATIONS

Impairment of neuromuscular transmission may be confirmed by a positive edrophonium (Tensilon) test. However, this traditional test has waned in popularity as it has high sensitivity but rather poor specificity.[52] Atropine 0.6 mg is given i.v. to prevent muscarinic side-effects, and this is followed by 1 mg edrophonium. If there is no obvious improvement within 1–2 minutes, a further 5 mg may be given. Some authors recommend the use of a saline placebo injection, and the presence of a second doctor as a ‘blinded’ observer. Resuscitation facilities should be available as profound weakness may ensue, especially in patients already receiving anticholinesterase drugs. Intramuscular neostigmine, 1–2 mg, may produce a positive response in 5–10% of patients who do not respond to edrophonium.[53]

The presence of autoantibodies against nicotinic ACh receptors (AChR) is quite specific, but false positives may occur in patients with penicillamine-treated rheumatoid disease, other autoimmune diseases and in some first-degree relatives of myasthenic patients.[54] About 20% of patients are seronegative. Some of these may have antibodies to muscle-specific kinase (MuSK), which appears to be associated with more severe, treatment-resistant disease, predominantly in women.

Electromyography shows characteristic changes in 90% of patients with generalised MG, and also in many patients with ocular symptoms only.

A syndrome of myasthenic weakness occurs in association with malignancy and other autoimmune diseases (Eaton–Lambert syndrome). Although fatigability is present, the pelvic and thigh muscles are predominantly affected, whereas ocular and bulbar involvement is rare. Tendon reflexes are reduced or absent, and there are specific electromyographic changes.

MANAGEMENT

1. *Symptomatic treatment* is provided by anticholinesterase drugs, which potentiate the action of ACh at receptor sites. Pyridostigmine (Mestinon) is the most commonly used, and is usually commenced at a dose of 60 mg orally four times daily. Considerable adjustment of dosage may be required.
2. *Corticosteroids* are effective in approximately 70% of patients, and give best results when high doses (e.g. prednisolone 50–100 mg/day) are used initially, and then gradually reduced. However, transient exacerbation upon commencement of steroids is very common,[55] and severely affected patients are often hospitalised for the initiation of therapy with gradually increasing doses. Older patients are more likely to respond, but an average of 4 months' treatment is required to achieve clinical stability and the majority will require continuing treatment indefinitely.[56]
3. *Azathioprine and cyclophosphamide* are both effective adjuncts to corticosteroid therapy. Overall, 80% of patients are improved, but this may be seen only after some months. A few patients may achieve complete remission.[57]
4. *Ciclosporin (cyclosporine),*[58] *mycophenolate and tacrolimus* are all supported by limited evidence in MG and are occasionally used.[59]
5. *Plasma exchange* is effective in producing short-term clinical improvement.[60] It is mainly used in myasthenic crisis or to improve severely affected patients before thymectomy. Its use should be considered, particularly in patients with severe respiratory failure refractory to conventional therapy (see below).[61] Typically, five exchanges of 3–4 litres each are performed over a 2-week period, and this results in improvement within days. However, the benefits are short-lived, lasting only weeks.[62]
6. *Intravenous immunoglobulin* has similar effects to those of plasma exchange. A dose of 400 mg/kg per day is usually given for 5 successive days, and occasional patients derive long-term benefit.[63] Interestingly, immunoglobulin has no consistent effect on ACh receptor antibody concentrations, and its mechanism of action is poorly understood. Clinical trial evidence suggests that immunoglobulin is as effective as plasmapheresis,[64] but some clinical experts continue to favour the latter, claiming the clinical response is more rapid.
7. *Thymectomy* offers the prospect of long-term, drug-free remission and has long been advocated as a mainstay of MG treatment. However, there is a lack of unequivocal clinical trial evidence to support its role.[59] Most experts advocate early thymectomy in younger patients with more than mild disease, regardless of the presence of a thymoma.[65]

   As with non-thymic surgery, preoperative optimisation of neuromuscular function is essential, using anticholinesterase drugs and steroids, supplemented by plasma exchange or immunoglobulin if necessary. Though anticholinesterase requirements are usually reduced in the immediate postoperative period to about three-quarters of the preoperative dose, sustained improvement following thymectomy may not be seen for months or even years. A thoracoscopic approach may achieve equivalent results with less short-term morbidity,[66] but the traditional sternotomy approach continues to be commonly used.[67]

MYASTHENIC AND CHOLINERGIC CRISIS

Patients with known MG may undergo life-threatening episodes of acute deterioration affecting bulbar and respiratory function. These may occur spontaneously, or may follow intercurrent infection, pregnancy, surgery, the administration of various drugs (**Box 57.5**),[68] or attempts to reduce the level of immunosuppression. Such episodes, known as myasthenic crises, usually resolve over several weeks, but occasionally last for months. The incidence of myasthenic crisis increases markedly with age.[69]

Rarely, a patient may deteriorate due to excessive dosage of anticholinesterase drugs ('cholinergic crisis'). Abdominal cramps, diarrhoea, excessive pulmonary secretions, sweating, salivation and bradycardia may be present, but these can also occur in patients with myasthenic crisis on high doses of pyridostigmine. Though the two situations may be difficult to distinguish, myasthenic crisis is far more likely unless extremely large doses of pyridostigmine (at least 120 mg every 3 hours) have been administered.

A Tensilon test is now considered an unreliable method of distinguishing between these two possibilities, may be hazardous, and is generally not recommended.

Patients with myasthenic crisis should be admitted directly to the ICU, as there is a significant risk of pulmonary aspiration due to bulbar involvement, bacterial pneumonia due to stasis, acute respiratory failure or cardiorespiratory arrest. After initial stabilisation and resuscitation, every effort should be made to identify and correct reversible causes, especially respiratory infections and electrolyte disturbances.

Box 57.5 Drugs that may exacerbate myasthenia gravis

Antibiotics	**Local anaesthetics**
Streptomycin	Procaine
Kanamycin	Lidocaine
Tobramycin	**General anaesthetics**
Gentamicin	Ether
Polymyxin group	**Muscle relaxants**
Tetracycline	Curare
Antiarrhythmics	Suxamethonium
Quinidine	**Analgesics**
Quinine	Morphine
Procainamide	Pethidine

Frequent estimations of vital capacity and maximum inspiratory force should be made and recorded. Tracheal intubation and mechanical ventilation should be considered in patients with significant bulbar involvement or clinical evidence of worsening respiratory failure. As with other neuromuscular disorders, deterioration of blood gases may occur late, and is an unreliable sign of progressive respiratory failure.[70] Aggressive chest physiotherapy, urinary drainage and nasogastric feeding may be required. Hypokalaemia, hypocalcaemia and hypermagnesaemia should be avoided, as all may exacerbate muscle weakness.

If the patient's clinical status cannot be rapidly improved by the adjustment of anticholinesterase dosage and aggressive treatment of intercurrent illness, high-dose corticosteroids and plasma exchange or immunoglobulin should be commenced simultaneously, and may produce some benefit within as little as 24 hours.[71]

PERIOPERATIVE MANAGEMENT

MG patients often require intensive care in relation to surgery for intercurrent illness or for thymectomy. Unstable patients should be admitted to hospital some days in advance for stabilisation. In severely affected patients, preoperative high-dose corticosteroids and/or plasma exchange may be used to improve the patient's fitness for surgery. It may be prudent to omit premedication, and an anaesthetic technique that avoids the use of non-depolarising muscle relaxants is usually advocated, though vecuronium and atracurium are probably safe in reduced dosage.[72,73] Suxamethonium can be used safely in normal dosage.[74]

Up to one-third of patients require continuing mechanical ventilation postoperatively following thymectomy. Predictive factors include a long preoperative duration of myasthenia, coexistent chronic respiratory disease, high anticholinesterase requirements (e.g. pyridostigmine >750 mg/day) and a preoperative vital capacity of less than 2.9 litres.[75] In those cases requiring mechanical ventilation, some authors advocate temporary cessation of anticholinesterase drugs to reduce respiratory secretions,[76] but generally they should be continued, though dosage requirements must be reassessed carefully and repeatedly.

MOTOR NEURON DISEASE (AMYOTROPHIC LATERAL SCLEROSIS, LOU GEHRIG'S DISEASE)

Motor neuron disease refers to a group of related disorders (**Box 57.6**), a few of which are clearly genetically determined, while most arise sporadically, are of completely unknown aetiology, and are generally untreatable. The most common variant is the sporadic form known as amyotrophic lateral sclerosis (ALS), a relentlessly progressive degenerative disease which most commonly affects males over 50 years of age.[78] In North America the term ALS is often used more generically, essentially equivalent to the broader term motor neuron disease.

PATHOGENESIS

The disease affects both upper and lower motor neurons. The involvement of either can predominate early on, giving rise to several clinically recognisable subgroups (see Box 57.6). The cerebral cortex as well as the anterior horns of the spinal cord are involved, with shrinkage, degenerative pigmentation and, eventually, disappearance of the affected cells accompanied by gliosis of the lateral columns ('lateral sclerosis'). As muscles are denervated, there is progressive atrophy of muscle fibres ('amyotrophy'), but, remarkably, sensory neurons as well as those concerned with autonomic function, coordination and higher cerebral function are all spared. The precise cause remains unknown. Postulated pathogenetic causes include oxygen free radicals, viral or prion infection, excess excitatory neurotransmitters and growth factors, and immunological abnormalities.[79] Heavy metal exposure has also been implicated. The only established clinical risk factors are age and family history.

CLINICAL PRESENTATION[80]

The earliest symptoms are those of insidiously developing limb weakness, often asymmetrical, accompanied by obvious muscle wasting. This classically affects the small muscles of the hand and may be accompanied by fasciculation. As time passes, the disease becomes more generalised and more symmetrical, with a mixture of upper and lower motor neuron signs (i.e. spasticity and hyperreflexia in addition to gross wasting), eventually involving bulbar and respiratory muscles. Awareness and intellect were previously thought to be preserved, but it is now recognised that up to half the patients have evidence of cognitive dysfunction.[81] Death occurs in 50% of cases within 3–5 years, usually due to

Box 57.6 Degenerative motor neuron disease[95]

respiratory infection, aspiration or ventilatory failure from profound weakness. However, there is wide variability, and a few patients may survive for many years.

DIAGNOSIS

There are no specific investigations, and the diagnosis must be made on clinical grounds together with electromyogram (EMG) evidence of denervation in at least three limbs. Experienced neurologists correctly diagnose the condition with 95% accuracy.[82] The most important differential diagnosis is multifocal motor neuropathy. The distinction is of clinical importance, as the latter is amenable to treatment. Poliomyelitis can also result in a syndrome of progressive weakness, wasting and fasciculation, beginning many years after the initial illness (the post-polio syndrome), and leading occasionally to respiratory failure and death.[83]

MANAGEMENT

Treatment is essentially symptomatic and supportive. No benefit has been shown with antioxidants, growth factors and immunosuppressants.[79] Current evidence suggests that non-invasive ventilation improves both quality of life and survival in patients who do not have severe bulbar dysfunction,[84] but the evidence favouring enteral tube feeding is much less convincing.[85] The centrally acting glutamate antagonist riluzole has been shown to slow slightly the progression of ALS.[86]

Admission to ICU is sometimes requested when these patients present with an acute deterioration or intercurrent illness. The intensivist may also be asked to assist with ambulatory or home respiratory support for gradually worsening chronic respiratory failure.

Respiratory support may be given by facemask, nasal mask or, rarely, by tracheostomy using simple, compact ventilators. Some patients require only intermittent support, particularly at night or during periods of acute deterioration due to intercurrent illness. Although home-based non-invasive ventilation has become routine, long-term invasive respiratory support outside the ICU is a major undertaking, requiring specific equipment and extensive liaison with the patient, the family and numerous specialised support services.

RARE CAUSES OF ACUTE WEAKNESS IN THE ICU

PERIODIC PARALYSIS[87]

This term describes a group of rare primary disorders, mostly inherited as autosomal dominant traits, producing episodic weakness. They must be distinguished from other causes of intermittent weakness, including electrolyte abnormalities, MG and transient ischaemic attacks. The inherited types are now grouped together with the various forms of myotonia and susceptibility to malignant hyperthermia. All are classified as congenital defects of skeletal muscle ion channels and there is an association with long QT syndrome and other cardiac channelopathies.[88] Symptoms begin early in life (before age 25), and follow rest or sleep rather than exertion. Alertness during attacks is completely preserved, and muscle strength between attacks is normal. Treatment is usually successful in preventing both the attacks and the chronic weakness, which can develop after many years in untreated patients.

The *hypokalaemic* form of periodic paralysis is predominantly inherited, but can also present sporadically in association with thyrotoxicosis. Involvement of bulbar or respiratory muscles occurs rarely. The degree of hypokalaemia during attacks is mild, but patients rapidly respond to potassium administration. Effective prophylaxis is conferred by acetazolamide, with potassium replacement. Many patients eventually develop established myopathy. Depolarising muscle relaxants should be avoided in these patients.

The *hyperkalaemic* form is milder, almost always inherited and rarely requires intensive care. The serum potassium is modestly elevated at the beginning of attacks, but may be normal at other times. CK may be elevated during attacks. Attacks respond to carbohydrate administration, sympathomimetics (which activate the sodium/potassium pump) and acetazolamide. Thiazide diuretics or acetazolamide provide effective prophylaxis. Non-depolarising muscle relaxants should be avoided in these patients.

A *normokalaemic* form and several eponymously named congenital syndromes are also included in this group of disorders.

BOTULISM[89]

Botulism is a widespread but very uncommon potentially lethal disease caused by exotoxins produced by *Clostridium botulinum* – an anaerobic, spore-forming Gram-positive bacillus. The vast majority of botulism is *foodborne* and outbreaks are largely due to home-preserved vegetables (type A toxin), meat (type B) or fish (type E), but high-risk foods also include low-acid fruit and condiments. Signs and symptoms are caused by toxin produced in vitro and then ingested.

The first recorded outbreak occurred in Germany in 1817, from ingestion of improperly preserved blood sausage (*Botulus* (Latin) = 'sausage').

Wound botulism arises rarely, when wounds (typically open fractures) are contaminated by soil containing type A or B organisms. Intravenous drug abusers are an increasing source of this condition through infected injection sites.

Infantile botulism arises in infants under 6 months of age, and is due to the active production of toxin by organisms in the gut rather than the direct ingestion of toxin.

Hidden botulism describes the adult equivalent of infantile botulism, and is a rare complication of various gastrointestinal abnormalities.

Inadvertent botulism is the most recently described form, and occurs as a complication of the medical or cosmetic use of botulinum toxin.

Inhalational botulism is the form that would occur as a result of aerosolised toxin released in the context of bioterrorism. Botulinum toxin (BoNT) is the most potent known neurotoxin, and some authors have estimated that as little as 1 gram of aerosolised BoNT could lead to the death of over 1.5 million people.[90]

In most cases, exogenously produced exotoxin is absorbed (primarily in the upper small intestine), and carried by the bloodstream to cholinergic nerves at the neuromuscular junction, postganglionic parasympathetic nerve endings and autonomic ganglia, to which it irreversibly binds. The toxin enters the nerve endings to interfere with ACh release.

Most patients become ill about 3 days after ingestion of toxin, with gastrointestinal symptoms (nausea, vomiting, abdominal pain, diarrhoea or constipation), dryness of the eyes and mouth, dysphagia and generalised weakness, which progresses in a symmetrical, descending fashion, with ventilatory failure in severe cases. Cranial nerve dysfunction is a prominent early feature, manifested by ptosis and diplopia, facial weakness and impaired upper airway reflexes. The pupils may be fixed and dilated in severe cases. Patients are usually afebrile and have no sensory involvement.

The differential diagnosis includes food poisoning from other causes, MG and GBS. Botulism can be confirmed by the presence of toxin (either in the patient's serum or stool, or in contaminated food) in about two-thirds of cases. Contact tracing, in the case of foodborne botulism, is of great importance.

Treatment is mainly supportive, with airway protection and mechanical ventilation when required. Mean duration of mechanical ventilation, when required, is 7 weeks. Clearance of toxin from the bowel with enemas and cathartics has been advocated. Guanidine hydrochloride, which enhances the release of ACh from nerve terminals, has been reported to improve muscle strength, especially in ocular muscles, and may be useful in milder cases.[91] Antibiotics have not been clearly shown to be useful. Equine antitoxins are available, but side-effects are common and their efficacy is limited. A human-derived antitoxin has been shown to be effective in *infantile botulism*,[92] and the United States Defense Department has a pentavalent antitoxin, which is not available for public use. Antitoxin must be given before the onset of paralysis in order to be effective. In *wound botulism*, antibiotics (penicillin or metronidazole) and aggressive debridement are recommended.

Most patients begin to improve after a week or so, but hospitalisation is usually required for 1–3 months. The mortality is low (5–8%) with good supportive care, including mechanical ventilation. Mild weakness and constipation may persist for many months.

Diabetic emergencies

Richard Keays

Diabetes mellitus is due to an absolute or relative deficiency of insulin. The sustained effect of poor glycaemic control results in a wide array of end-organ damage as a consequence of small- and large-vessel pathology. Mortality and morbidity are related to the progress of this damage but often there are acute metabolic deteriorations that can be life-threatening. Diabetic ketoacidosis (DKA) and hyperosmolar hyperglycaemic state (HHS) are two of the most common acute complications of diabetes, both accompanied by hyperglycaemia. The pathophysiological changes that occur in both disease states represent an extreme example of the super-fasted state. Coma may also result from severe hypoglycaemia due to overtreatment – usually with insulin.

DIABETES MELLITUS

Type I insulin-dependent diabetes mellitus (IDDM) has a peak incidence in the young rising from 9 months to 14 years and declining thereafter. In 25% of patients the presentation is with ketoacidosis, especially in those under 5 years of age. Usually the fasting plasma glucose is >7.8 mmol/L and glucose and ketones may be present in the urine. In the asymptomatic patient with an equivocal fasting plasma glucose, an impaired glucose tolerance test may be demonstrated.

Type II non-insulin-dependent diabetes mellitus (NIDDM) is prevalent in the elderly but can occur at any age. Truncal obesity is a risk factor and there is ethnic variation in susceptibility. Diagnosis is often delayed and may be incidental from blood or urine sugar screening.[1] Increasingly it is recognised that individuals can be in a prediabetic state of impaired glucose regulation for many years, which makes them 5 to 15 times more likely to progress to diabetes. It may present with classical symptoms, as a diabetic emergency, with complications of organ damage or vascular disease.

EPIDEMIOLOGY

The worldwide prevalence of diabetes is estimated to be 366 million people in 2011. Diabetes mellitus affects about 6% of the world's population and is set to rise to 552 million sufferers by 2030.[2] Most of these (97%) will have type II diabetes but the resources required to treat the complications of type I diabetes are such that health care costs are equivalent between the two groups. The annual incidence of DKA is around 14 episodes per thousand patients with diabetes and it has been estimated in the USA that about $1 billion are spent each year in treating DKA. Hospital admissions for DKA have gone up by 30% in the last decade and this is most likely due to the increase in ketosis-prone type II diabetics. HHS represents approximately 1% of primary admissions to hospital with diabetes as compared with DKA. The mortality rate in HHS remains high at 5–20%, whereas the mortality in DKA has been falling dramatically in recent years and is less than 1% but still remains high in the elderly.[3] An interplay of both genetic and environmental factors contribute to disease development. In type I diabetes there is some evidence for genetic susceptibility but environmental factors play a greater part. It varies across race and regions, being highest in northern Europe and the USA and lowest in Asia and Australasia. Genetic factors in type 2 diabetes are evidently crucial, with a concordance between monozygotic twins approaching 100%.

PATHOGENESIS

Normal carbohydrate metabolism depends upon the presence of insulin (**Fig. 58.1**). However, different tissues handle glucose in different ways; for example, red blood cells lack mitochondria and therefore pyruvate dehydrogenase and the enzymes involved in β-oxidation, whereas liver parenchymal cells are able to perform the full range of glucose disposal (**Fig. 58.2**). Both DKA and HHS result from a reduction in the effect of insulin with a concomitant rise in the counterregulatory hormones such as glucagon, catecholamines, cortisol and growth hormone. Hyperglycaemia occurs as a consequence of three processes: increased gluconeogenesis, increased glycogenolysis and reduced peripheral glucose utilisation. The increase in glucose production occurs in both the liver and the kidneys as there is a high availability of gluconeogenic precursors such as amino acids (protein turnover shifts from balanced synthesis and degradation to reduced synthesis and increased degradation). Lactate and glycerol also become available owing to an increase in skeletal muscle glycogenolysis and an increase in adipose tissue

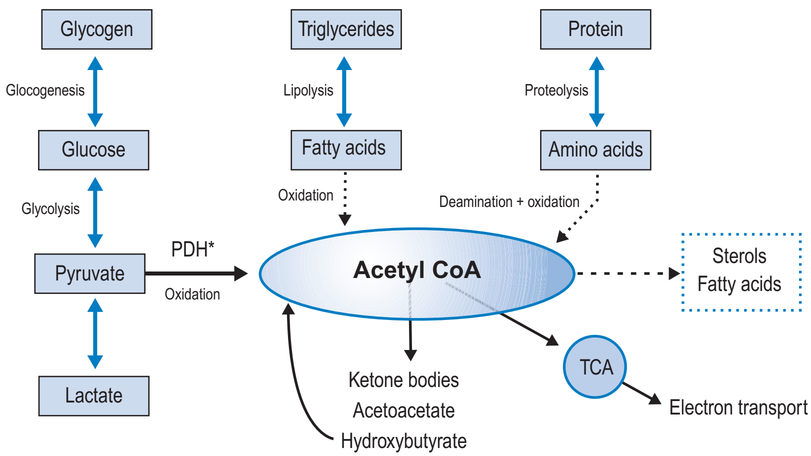

Figure 58.1 Sources and fate of acetyl CoA. *Pyruvate conversion by pyruvate dehydrogenase (PDH) is essentially irreversible, therefore no net conversion of fatty acids to carbohydrates can occur. TCA=tricarboxylic acid.

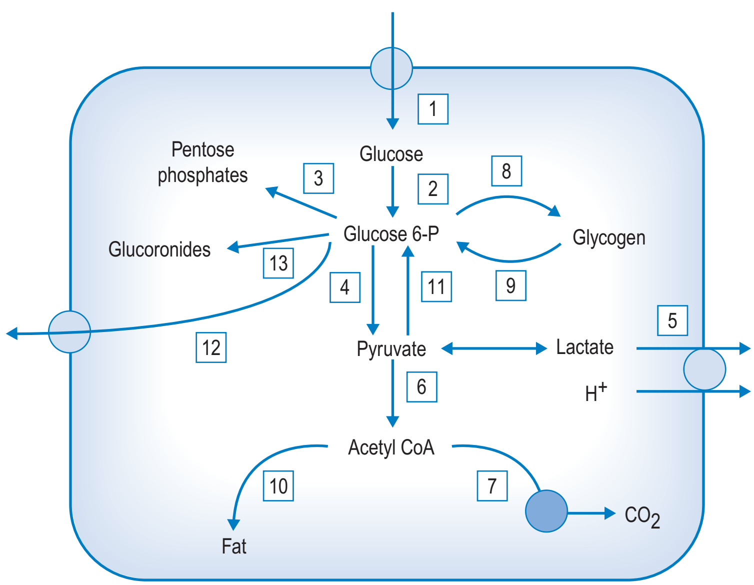

Figure 58.2 Glucose metabolism within hepatocyte: (1) glucose transport GLUT-1; (2) hexokinase phosphorylation; (3) pentose phosphate pathway (hexose monophosphate shunt); (4) glycolysis; (5) lactate transport out of cell; (6) pyruvate decarboxylation; (7) tricarboxylic acid cycle; (8) glycogenesis; (9) glycogenolysis; (10) lipogenesis; (11) gluconeogenesis; (12) glucose-6-phosphate (G 6-P) hydrolysis and release of glucose; (13) glucuronidation.

lipolysis respectively. Lastly, there is an increase in gluconeogenic enzyme activity enhanced further by stress hormones. Although hepatic gluconeogenesis is the main mechanism for producing hyperglycaemia a significant proportion can be produced by the kidneys.[4] What is unclear is the temporal relationship of these changes, although an increase in both catecholamines and the glucagon/insulin ratio are early features.[5]

Decreased insulin and increased epinephrine levels activate adipose tissue lipase causing a breakdown of triglycerides into glycerol and free fatty acids (FFAs). Once again glucagon is implicated as hepatic oxidation of FFAs to ketone bodies is stimulated predominantly by its inhibitory effect on acetyl-CoA carboxylase. The resultant reduced synthesis of malonyl-CoA causes a disinhibition of acyl-carnitine synthesis and subsequent promotion of fatty acid transport into mitochondria where ketone body formation occurs. Both cortisol and growth hormone are capable of increasing FFA and ketone levels and once again the exact contribution of insulin deficiency or stress hormone increase to ketogenesis is undetermined. As ketone bodies are comparatively strong acids, a large hydrogen ion load is produced owing to their dissociation at physiological pH. The need to buffer hydrogen ions depletes the body's alkali reserves and ketone anions accumulate, accounting for the elevated plasma anion gap.

By contrast, HHS does not share the ketogenic features of DKA. Reduced levels of FFAs, glucagon, cortisol and growth hormone have been demonstrated in HHS relative to DKA although this is by no means a consistent observation. However, the presence of higher levels of C-peptide in HHS (with lower levels of growth hormone) relative to DKA suggests there is just enough insulin present in HHS to prevent lipolysis but not enough to promote peripheral glucose utilisation.[6]

Hyperosmolarity, which is a prominent feature of HHS, is caused by the prolonged effect of an osmotic

diuresis with impaired ability to take adequate fluids. It has been shown that, even when well, patients who have suffered from HHS have impaired thirst reflexes. However, the hyperosmolarity seen in about one-third of patients with DKA results from a shorter osmotic diuresis and to variable fluid intake due to nausea and vomiting – which is often ascribed to the brainstem effects of ketones.

Interestingly, hyperglycaemia with or without ketoacidosis leads to a significant increase in pro-inflammatory cytokine production, which resolves when insulin therapy is commenced.[7] This has led others to postulate a wider beneficial anti-inflammatory effect attributable to insulin therapy. This pro-inflammatory, pro-thrombotic state may explain the relatively high incidence of thrombotic events associated with diabetic emergencies.

CLINICAL PRESENTATION

DKA and HHS represent the two extremes of presentation due to the absolute or relative deficiency of insulin. However, up to one-third of cases can present with mixed features.[8] DKA develops over a shorter time period whereas HHS appears more insidiously – see **Table 58.1**. Polyuria, polydipsia and weight loss are experienced for a variable period prior to admission and, in patients with DKA, nausea and vomiting are also common symptoms. Abdominal pain is commonly seen in children and occasionally in adults and may mimic an acute abdomen. Dehydration presents with loss of skin turgor, dry mucous membranes, tachycardia and hypotension. Mental obtundation occurs more frequently in HHS than DKA as more patients, by definition, are hyperosmolar and the presence of stupor or coma in patients who are not hyperosmolar requires consideration of other potential causes for altered mental status.[9] However, loss of consciousness is not a common presentation with DKA or HHS (<20%). Most hospitalisations are caused by infection (29%) or non-compliance with medication (17%) in previously diagnosed diabetics; however, in some patients it is the first presentation with undiagnosed diabetes (17%).[10] Given that there is a high likelihood of concurrent infection, most patients have a normal or low temperature and most patients also have a leucocytosis, whether there is infection present or not.

Table 58.1 Comparison of DKA and HHS

PRESENTATION	DKA	HHS
Prodromal illness	Days	Weeks
Coma	++	+++
Blood glucose	++	+++
Ketones	+++	0 or +
Acidaemia	+++	0 or +
Anion gap	++	0 or +
Osmolality	++	+++
TYPICAL DEFICITS		
Total water (litres)	6	9
Water (mL/kg)	100	100–200
Na^+ (mEq/kg/kg)	7–10	5–13
Cl^- (mEq/kg/kg)	3–5	5–15
K^+ (mEq/kg/kg)	3–5	4–6
PO_4^{3-} (mEq/kg/kg)	5–7	3–7
Mg^{2+} (mEq/kg/kg)	1–2	1–2
Ca^{2+} (mEq/kg/kg)	1–2	1–2

DIABETIC KETOACIDOSIS

This tends to occur more often in patients with type I diabetes, although a third of hospitalisations for DKA occurs in patients with type 2 diabetes. The predominant feature is ketoacidosis. Rapid, deep breathing due to the acidosis (Kussmaul breathing) may be present, as may the breath odour that is characteristic of ketones, which is somewhat like nail polish remover. Insulin therapy omission or inadequate dosing is the commonest precipitant of DKA (40%) with underlying infection the next most likely cause (30%).[6] Other causes should be actively sought such as silent myocardial infarction, pancreatitis and drugs that interfere with carbohydrate metabolism. Diagnostic criteria include pH<7.3, HCO_3^- <15 mmol/L and blood glucose >14 mmol/L. Increasing acidaemia, ketonaemia and deteriorating conscious level indicate an increasing severity. Blood glucose per se is not a good determinant of severity and euglycaemic ketoacidosis is possible, depending on the hepatic glycogen stores *prior* to the onset of DKA – a patient who has not been eating well in the recent past may well have a minimally elevated blood glucose. A high amylase is frequently seen and may be extrapancreatic in origin. It should be interpreted cautiously as a sign of pancreatitis.

HYPEROSMOLAR HYPERGLYCAEMIC SYNDROME

HHS is more often seen in patients with type II diabetes and the dominant feature is hyperosmolarity (>320 mOsm/kg). HHS is typically observed in elderly patients with non-insulin-dependent diabetes mellitus, although it may rarely be a complication in younger patients with insulin-dependent diabetes, or those without diabetes following severe burns,[11] parenteral hyperalimentation, peritoneal dialysis, or haemodialysis. Patients receiving certain drugs including diuretics, corticosteroids, β-blockers, phenytoin and diazoxide

are at increased risk of developing this syndrome. HHS may be caused by lithium-induced diabetes insipidus.[12] Not only may mental obtundation occur, but also occasionally focal neurological features or seizures are present.

MANAGEMENT

ICU admission is indicated in the management of DKA, HHS and mixed cases in the presence of cardiovascular instability, inability to protect the airway, altered sensoria and the presence of acute abdominal signs or symptoms suggestive of acute gastric dilatation. It is now possible to direct therapy to the underlying metabolic problems of ketogenesis and acidosis rather than the surrogate marker of the blood glucose level. This is increasingly important in euglycaemic DKA. Assessment of response to therapy guided by measurement of ketone concentration is becoming part of best practice.[13]

INITIAL ASSESSMENT

These conditions are medical emergencies and a prompt and thorough history and physical examination should be obtained with special attention paid to airway patency, conscious level, cardiovascular and renal status, possible sources of infection and state of hydration. Some assessment of the severity of DKA is also aided by the degree of acidosis. The majority of patients have a leucocytosis irrespective of whether or not they have a source of sepsis. Attention must also focus on any underlying precipitant. The two major factors involved are inadequate insulin treatment and infection causing a change in insulin responsiveness. The latter must be actively sought in the management of these patients.

FLUID REQUIREMENTS

Dehydration and sodium depletion develop as a result of the osmotic diuresis that accompanies hyperglycaemia in both DKA and HHS. In DKA there is an additional ketoanion excretion, which is approximately half that of glucose. This obligates cation (sodium, potassium and ammonium) excretion and contributes to the electrolyte losses. Despite the dual osmotic load of glucose and ketones in DKA, dehydration is often worse in HHS owing to the more prolonged onset. Insulin itself also promotes salt, water and phosphate reabsorption in the kidney and its lack can contribute further to these losses. The total osmolar load on the kidney in DKA can be as much as 2000 mOsm/day.[14] Fluid resuscitation is initially directed to repleting the intravascular volume, and colloids achieve this more rapidly than crystalloids. Fluids alone will reduce glucose and counterregulatory hormone levels and diminish peripheral insulin resistance. There is individual variation as to how much fluid will be required and simple vital signs such as heart rate, blood pressure and peripheral perfusion should guide the resuscitation. Fluid challenges with assessment of response may be less likely to avoid the problems of fluid overload. The usual urinary sodium concentration is 60–70 mmol/L, which is roughly similar to half-normal saline and this is the logical fluid to use for rehydration.[15] This avoids too great a sodium load and is less likely to produce a hyperchloraemic acidosis, which, if rhabdomyolysis occurs, will further acidify the urine and promote precipitation of myoglobin in the renal tubule. As insulin therapy is commenced extracellular water is driven into the intracellular compartment, exacerbating hypovolaemia, which is why it is most important to commence fluid resuscitation early. This can also lead to a rapid rise in serum sodium concentrations as the true sodium in hyperglycaemia is higher than the measured sodium. Such rapid changes in sodium levels can lead to prolonged neurological dysfunction such as pontine myelinolysis.[16]

Inappropriate fluid replacement can lead to problems. Studies of DKA and cerebral oedema are limited but there is some evidence that overaggressive replacement of water losses can precipitate cerebral and other forms of oedema. Water losses do not need to be corrected rapidly and hyperosmolality should not be corrected more rapidly than 3 mOsm/kg H_2O/h.

General guidelines are given in **Figure 58.3** but it must be remembered that each case needs individual tailoring of treatment. It is mostly agreed that the first litre should be isotonic saline, even in patients with marked hypertonicity. This should be given over the first hour. If there is any evidence of cardiovascular compromise due to hypovolaemia, plasma expansion with colloids should also be given as a matter of urgency. That saline has a pH of 5.5 and a high chloride content is a source of some concern as a resolving ketoacidosis would be compounded by a hyperchloraemic acidosis. A recent study using a balanced electrolyte solution has shown reduced resuscitation-associated hyperchloraemia and an improved serum bicarbonate level.[17] For the next 2 hours 0.45% saline can be given if the serum sodium is normal or high. If the corrected sodium is low then 0.9% saline should be continued. When the blood glucose falls below 15 mmol/L in DKA or HHS then a combination of 5 or 10% dextrose solution with some further saline-containing solution should be commenced (100–250 mL/h) and continued until the ketonaemia has resolved. Assuming cardiovascular stability, the aim should be to correct the remaining fluid deficit gradually over the next 24–48 hours whilst also taking account of ongoing urinary losses.

INSULIN THERAPY

Low-dose, physiological insulin replacement resolves the biochemical abnormalities as quickly as higher

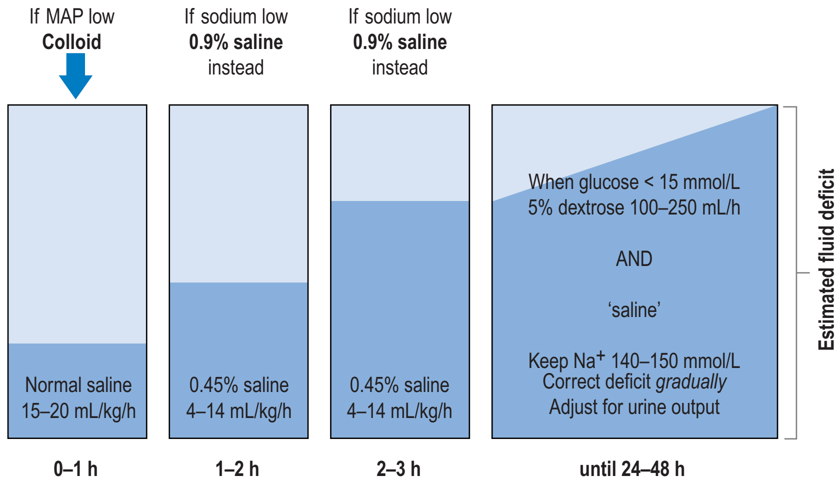

Figure 58.3 Fluid regimen in hyperglycaemic emergencies. No major differences between DKA and HHS. MAP=mean arterial pressure.

doses without running the risk of hypoglycaemia and hypokalaemia, and gradual correction of hyperglycaemia is associated with a lower mortality.[18] A recent study has even questioned the need for an initial insulin bolus dose, contending that commencing the infusion at 0.14 U/kg/h may well be sufficient. A bolus dose (0.14 U/kg) may be required after 1 hour if the blood glucose level has not fallen by at least 10%.[19] Alternatively, a regimen consisting of an initial bolus dose of 0.1 U/kg followed by low dose (0.1 U/kg/h) insulin infusion is similarly acceptable and safe. Weight-based fixed infusion rates are preferable to sliding-scale regimens. Intravenous rather than subcutaneous or intramuscular delivery is preferable as glucose decrement is the same whatever route is chosen, but intravenous insulin reduces ketone body production faster. It is mandatory to use the intravenous route where hypovolaemic shock is present. The aim of treatment is to achieve metabolic targets, specifically: increasing bicarbonate concentration by 3 mmol/L/h, reducing the blood glucose concentration by 3 mmol/L/h and reducing the blood ketone concentration by 0.5 mmol/L/h whilst maintaining normal potassium levels. If the glucose levels fail to reduce appropriately it may indicate insufficient fluid resuscitation. Severe insulin resistance occurs in 10% of cases and will necessitate the use of higher doses. The insulin infusion rate should be reduced to 0.02–0.05 U/kg/h when the glucose level falls to below 12 mmol/L (DKA) or below 15 mmol/L (HHS), and maintained at a level tailored to the patient's need.

ELECTROLYTE THERAPY

POTASSIUM

Hyperosmolarity causes a shift of potassium from within cells to the extracellular space and this potassium is lost as a result of the osmotic diuresis. Renal losses are augmented by secondary hyperaldosteronism and ketoanion excretion as potassium salts. Typical total body deficits are shown in Table 58.1. Serum potassium levels may initially be high and potassium replacement should not commence until this has fallen to <5.5 mmol/L. Potassium can be replaced as a combination of the chloride and phosphate salt as this can avoid hyperchloraemia and hypophosphataemia. Occasionally the presenting potassium level will be low (<3.3 mmol/L), which represents profound potassium depletion (600–800 mmol) and replacement should commence immediately and before insulin therapy is initiated. If the patient is in between these two levels then 20–40 mmol of potassium may be given in the first hour – this should not generally be exceeded. Further decisions regarding potassium replacement need to be adjusted with respect to serum levels and the urine output but usually 20–30 mmol/h are required. ECG monitoring has been recommended where potassium replacement is needed for patients who present with hypokalaemia or cardiac rhythms other than sinus tachycardia.[6]

PHOSPHATE

A total body phosphate deficit of greater than 1 mmol/kg is typical. Once again the shift is from the intracellular compartment with subsequent urinary loss; however, serum levels are typically normal or increased. Insulin causes an intracellular shift of phosphate and, although hypophosphataemia rarely results in adverse complications, muscle weakness, haemolytic anaemia and impaired cardiac systolic performance can occur. Routine phosphate replacement has not been shown to be beneficial in DKA,[20] but correction of severely low levels (<0.4 mmol/L) may be necessary. Excessive phosphate replacement leads to hypocalcaemia and serum calcium should be monitored.

MAGNESIUM

A chronic magnesium deficiency may be present in type I or II diabetes and may be exacerbated by renal impairment. The benefits of magnesium replacement have not been demonstrated in diabetic emergencies, but the principles of magnesium supplementation are similar to other critical care situations.

CORRECTION OF ACIDOSIS

This occurs more slowly than the correction of blood glucose but the use of bicarbonate in DKA remains controversial. Experimentally, metabolic acidaemia impairs myocardial contractility, affects oxyhaemoglobin dissociation and tissue oxygen delivery, alters cellular metabolism, inhibits intracellular enzymes, such as the pH-dependent enzyme phosphofructokinase, and results in organ dysfunction. Not only that, but insulin resistance increases sharply below pH 7.2. Bicarbonate treatment to rapidly correct the acidosis should offer some benefit but, in most studies, the use of sodium bicarbonate fails to provide any benefit. There are no haemodynamic benefits that could not be attributed purely to osmotic load of sodium administered.[21] There is no doubt that blood pH can be improved but at the expense of worsening the intracellular acidosis.[22] Sodium bicarbonate treatment may cause paradoxical cerebrospinal fluid (CSF) acidosis.[23] It is also associated with other side-effects that may overshadow any potential benefits such as: increased CO_2 production, hypokalaemia, rebound alkalosis, volume overload and altered tissue oxygenation. In the context of DKA, sodium bicarbonate also delays the clearance of ketones and may enhance further hepatic production even when insulin and glucose are being delivered.[24] At pH>7.0 insulin will block lipolysis and ketoacid production; however, when the pH is between 6.9 and 7.1 it remains uncertain whether bicarbonate is beneficial or otherwise. Although a recent systematic review of trials in both adult and paediatric populations concluded that there was no obvious benefit with bicarbonate treatment, there were reassuringly few clinically significant complications resulting from its use either.[23] These studies did not include patients with pH<6.85 and recommendations in such patients are difficult. Below pH 6.9 most authorities would recommend the use of bicarbonate to correct the pH partially to the threshold. The threshold for correction is debatable (between pH 6.9 and 7.15) but life-threatening hyperkalaemia is an undisputed indication for bicarbonate therapy.

Sometimes there is a persistent acidosis without ketosis. Regeneration of bicarbonate in DKA once insulin activity has been restored occurs via two mechanisms: renal and hepatic. The latter requires a metabolisable substrate, typically ketones, which are lost to the body especially if the diuresis is substantial. The former is slow and hyperchloraemia may persist, particularly if a high-chloride-containing fluid such as normal saline is used.[25]

MONITORING

The following monitoring parameters are also undertaken as investigations on presentation:

1. *Blood glucose concentration:* initially every hour, then less frequently
2. *Blood urea and creatinine concentrations:* on admission and then at least daily. Creatinine assays that rely on a colorimetric method may be interfered with by the presence of acetoacetate, giving a falsely elevated value
3. *Serum electrolytes:*
   a. *Serum sodium*: on admission and at least daily. It represents the relative water and electrolyte losses and cannot be used to infer a state of hydration. It may be normal (50% of cases), raised or lowered. Each 1.0 mmol/L rise in blood glucose will decrease serum sodium by 0.3 mmol/L, so hypernatraemia represents a profound loss of water
   b. *Serum potassium*: initially every hour, then less frequently (every 2–4 hours). DKA patients have a K^+ deficit of 3–5 mmol/kg. However, serum concentrations are usually normal or raised because of a shift from the intracellular to the extracellular compartment due to acidaemia, insulin deficiency and hypertonicity. Hypokalaemia on admission represents severe potassium depletion (>600–800 mmol) and requires potassium administration before starting insulin therapy
   c. *Serum chloride*: as indicated
   d. *Serum phosphate*: on admission and every 1–2 days. Routine replacement is not of any benefit. Despite evidence that hypophosphataemia leads to a decrease in 2,3-diphosphoglycerate levels, subsequent correction has no impact on the oxyhaemoglobin dissociation curve and dangerous hypocalcaemia may result[20]
   e. *Serum magnesium*: on admission and every 1–2 days. Chronic hypomagnesaemia may be present and may contribute to insulin resistance, carbohydrate intolerance and hypertension. Severe uncontrolled diabetes also results in magnesium depletion. However, the benefits of replacement therapy have not been demonstrated but may be necessary if arrythmias are present
4. *Serum ketones (if available):* on admission. This test relies on the nitroprusside reaction and, because it measures acetoacetate and acetone but not β-hydroxybutyrate, which is the main ketoacid in DKA, it consequently underestimates the degree of ketoacidosis. Near patient testing for β-hydroxybutyrate is now more readily available

5. *Urinary glucose and ketones:* 4-hourly; ketonuria may persist up to 2 days after the correction of acidosis due to the presence of acetone, which is not an acid anion and is highly lipid soluble. The ratio of acetoacetate : β-hydroxybutyrate (approximately 1 : 3) increases as acidosis improves with treatment; this can lead to the paradoxical impression that ketosis is worsening but is merely an anomaly of the nitroprusside test
6. *Arterial blood gases:* frequently, as indicated
7. *Serum osmolality and anion gap:* initially and as indicated. Serum osmolality can be measured with an osmometer or estimated
8. *Serum lactate:* if acidosis is severe and anion gap is large
9. *Full blood count and coagulation studies:* daily and as indicated. Leucocytosis with left shift may occur in the absence of sepsis
10. *Chest X-ray*
11. *Blood cultures, urine and sputum microscopy and culture and culture of relevant specimens:* as indicated
12. *Pulse oximetry:* continuously
13. *Electrocardiogram:* 12-lead recording and continuous monitoring
14. *Invasive haemodynamic monitoring:* as indicated
15. *Neurological status and observations:* including Glasgow Coma Scale and computed tomography (CT) scans as indicated for persistent coma or worsening neurological state
16. *Other investigations:* as indicated (e.g. liver function tests, serum amylase, cardiac enzymes and creatinine clearance).

COMPLICATIONS

EARLY

The commonest early complications are hypoglycaemia due to overtreatment with insulin, hypokalaemia due to inadequate replacement and hyperglycaemia due to interruption of insulin. A hyperchloraemic acidosis can develop in about 10% of patients with DKA. It can be exaggerated by excessive saline use and is not usually clinically significant except in cases of acute renal failure or extreme oliguria.

Clinically apparent cerebral oedema is a rare (0.5–1%) but extremely serious complication of DKA occurring predominantly in children and the mortality is high (25%), with a quarter of survivors being left with some permanent neurological sequelae. Recent studies have suggested a subclinical incidence approaching 50%.[26] Risk factors for developing cerebral oedema include: degree of hypocapnia and dehydration, the failure of serum sodium to rise with treatment and the use of sodium bicarbonate.[27] It also occurs in young adults and may be associated with rapid deterioration in conscious level with or without seizures. If progressive signs of brainstem herniation are present the mortality is high with only 7–14% likely to make a complete recovery. The risks of brain herniation are related to the degree of acidosis and the volume of initial fluid resuscitation. Oedema formation most likely occurs due to a vasogenic mechanism[28] and cerebral hyperaemia with loss of autoregulation is evident, which can take up to 36 hours to resolve.[29,30] It has been recommended that plasma osmolality is reduced slowly and that glucose must be added to the hydrating fluids when the plasma glucose has fallen below 15 mmol/L in DKA and HHS. Fatal cases of cerebral oedema have been reported in HHS as well and treatment is aimed at maintaining plasma osmolality with intravenous mannitol.

Some degree of brain dysfunction is apparent even in those patients who are not comatose but who have severe DKA as measured by sensory evoked potentials. This reverts to normal with correction of the ketoacidosis.[31]

Hypoxia, non-cardiogenic pulmonary oedema and myocardial infarction can also occur – particularly in the elderly.

INTERMEDIATE

A reversible critical illness motor syndrome has been described in HHS and led to slowness to wake up and reversible tetraplegia.[32] Deep venous thrombosis and pulmonary embolism occur more frequently in DKA and are a significant cause of mortality in HHS.[33,34] Prophylaxis with subcutaneous heparin is advisable. Full anticoagulation may be indicated in HHS.[3]

LATE

Various movement disorders can rarely persist after recovery from HHS.[35] The effects of neuroglycopenia can result in an array of late complications from amnesia to optic atrophy.

PROGNOSIS

In a series of 610 patients with DKA or HHS the overall mortality was 6.2%. HHS is a more serious disease and has an associated mortality 2–3 times higher than DKA; nevertheless DKA is approximately six times commoner. A retrospective analysis of causes of death in this group of patients revealed that pneumonia was the commonest cause of death (37%), followed by myocardial infarction (21%), with mesenteric or iliac thrombosis accounting for 16% of deaths.[36] Rhabdomyolysis has been reported in both DKA and HHS and, when present, increases the mortality.[37] The likelihood of a poorer outcome in HHS was associated with: older age, low blood pressure, low sodium, pH and bicarbonate plasma levels, and high urea plasma levels, of which urea has the strongest association.[38] Mortality is also

age-related in DKA. Pregnant women with type I diabetes are more likely to have a worse outcome from DKA than non-pregnant diabetic women who develop DKA. The presence of hypothermia is also a poor prognostic sign.

Survival depends upon establishing a high index of suspicion and a rapid diagnosis.[39]

HYPOGLYCAEMIC COMA

This results from overtreatment with insulin and is the commonest cause of diabetic coma. Clinically, there is confusion, agitation progressing to coma and fitting. Tremor, tachycardia and sweating may be blunted by diabetic autonomic neuropathy. It may be precipitated in known type I diabetic patients (up to 10% of patients per year) by missed meals, exercise and overdose of insulin or oral hypoglycaemic agents. Changing therapy or insulin periods are susceptible periods and there is an increased risk associated with long-acting sulfonylurea agents. Alcoholic ketoacidosis is a syndrome of hypoglycaemia, ketoacidosis and dehydration associated with starvation, vomiting, upper abdominal pain and neurological changes including seizures and coma. Hypoglycaemia may complicate other disease states (e.g. liver and renal failure, or adrenocortical insufficiency).

Severe hypoglycaemia (blood glucose <1 mmol/L) is a medical emergency. Brain metabolism uses half the glucose produced by the liver and neuronal stores of glycogen are depleted within 2 minutes, after which the brain is susceptible to damage. Urgent glucose infusion (50 mL of 50% glucose) is required and leads to rapid resolution of coma. Intramuscular glucagon is an alternative especially suited to out-of-hospital circumstances, but achieves a slower result when compared with intravenous glucose.[40] Hypoglycaemia due to long-acting insulins or oral hypoglycaemic agents will require ongoing glucose infusion.

Diabetes insipidus and other polyuric syndromes

Alastair C Carr

Diabetes insipidus (literal translation 'tasteless siphon') refers to a syndrome characterised by pathological polyuria, excessive thirst and polydipsia. Polyuria is arbitrarily defined as a urine loss of >3 litres per day in an adult of normal mass or >2 L/m^2 in children. The urine produced in DI is inappropriately dilute having both low specific gravity and low osmolality in the face of a high or normal plasma osmolality.

Three subtypes of DI are recognised: (i) *nephrogenic DI* – caused by insensitivity of the kidney to antidiuretic hormone (ADH), (ii) *central/hypothalamic/neurogenic DI* – caused by reduced or absent production of ADH, and (iii) *gestational DI* – caused by an increase in the placental production of vasopressinase or as a variant of central or nephrogenic DI developing during pregnancy. A separate disorder is occasionally classified as a fourth form of DI: *primary polydipsia* (also called psychogenic or neurogenic polydipsia or polydipsic DI). This is caused by excessive water ingestion usually due to psychological disturbance but occasionally associated with a lesion of the hypothalamus. In the context of hospital in-patients, a similar iatrogenic condition is created by overenthusiastic administration of intravenous solutions of dextrose 5% or hypotonic saline. Although water overload will reduce plasma osmolality and reduce the ability of the kidney to maximally concentrate urine, the diuresis of hypo-osmolar urine seen with water overload is not pathological but physiological and appropriate. In this instance, plasma osmolality is low or in the low–normal range and the body is attempting to restore plasma osmolality to normality by reducing water reabsorption in the kidneys and inducing a water diuresis.

In critically ill patients, polyuria may be the sole part of the DI syndrome apparent to the clinician. Patients are seldom in control of their own fluid intake and are frequently unable to report thirst. The recognition of DI is important as failure to recognise and treat the syndrome appropriately will result in severe dehydration and hyperosmolality with a significant risk of morbidity and mortality. As there are many causes of polyuria in the critically ill (**Box 59.1**), it is important to adopt a systematic approach to the clinical assessment, investigations, diagnosis and management of such patients.

The classification as a solute or water diuresis is not always absolute; the table provides a convenient structure but a diuresis should be considered in terms of the individual patient and both physical and biochemical assessments. A diuresis may frequently represent the clearance of both an excess of water and solute such as is usually the case following the resolution of septic shock with multi-organ failure.

BACKGROUND PHYSIOLOGY AND ANATOMY

OSMOLALITY

Osmolality is the measure of osmoles (Osm) of solute per kilogram of solvent and includes both permeant (e.g. urea) and impermeant solutes (e.g. sodium). It may change owing to both water movement and the movement of permeant solute. Osmolarity is the measure of osmoles per litre of solute and, unlike osmolality, is temperature dependent. Normal plasma osmolality is in the range of 275–295 mOsm/kg. Plasma osmolality can be estimated from several equations.[1] The formula of Worthley[2] below is both simple and correlates well with measured values.[3]

$$\text{plasma osmolality (mOsm/kg)} = 2\,[\text{Na+}] + [\text{urea}] + [\text{glucose}]$$

All units of solute are mmol/L.

Where a patient is markedly uraemic, a value of 8 mmol/L is substituted for the actual urea. Actual osmolality may differ markedly from estimated osmolality in the presence of unmeasured, osmotically active solutes such as mannitol, ethanol, bicarbonate, lactate and amino acids. Whenever concern exists that a patient may be hyper- or hypo-osmolal, osmolality should be measured by assessing the freezing point depression of the plasma or urine. Increasing the osmolality results in depression of the freezing point.

The osmolal gap is the difference between the calculated and measured osmolality in plasma or urine. The normal osmolal gap is <10 mOsm/kg. An increased osmolal gap indicates the presence of an unmeasured osmotically active solute.

TONICITY

Tonicity describes the ability of a solution of impermeant solute (such as sodium) to cause the movement

Box 59.1 Causes of polyuria

Water diuresis

Pathological: Diabetes insipidus – cranial, nephrogenic, gestational

Physiological:

- Psychogenic polydipsia (excess drinking is pathological but the diuresis is not)
- Iatrogenic – excessive administration of hypotonic solutions (e.g. 5% dextrose solution, 0.45% saline, 0.18% saline 4% dextrose solutions)

Solute diuresis

Pathological:

- Hyperglycaemia, azotaemia (uraemia), Fanconi syndrome, renal tubular acidosis, glomerulonephritis, hyperaldosteronism, Addison disease, anorexia nervosa, migraines, paroxysmal tachycardia (via increased ANP release)
- Poisons/drugs – ethanol, methanol, ethylene glycol, mannitol, loop diuretics, thiazide diuretics

Physiological:

- Resolving sepsis (redistribution of fluid into the vascular compartment from the third space)
- Iatrogenic – excessive administration of isotonic or hypertonic solutions e.g. 0.9% saline, hypertonic saline, Hartman's solution, Gelofusin

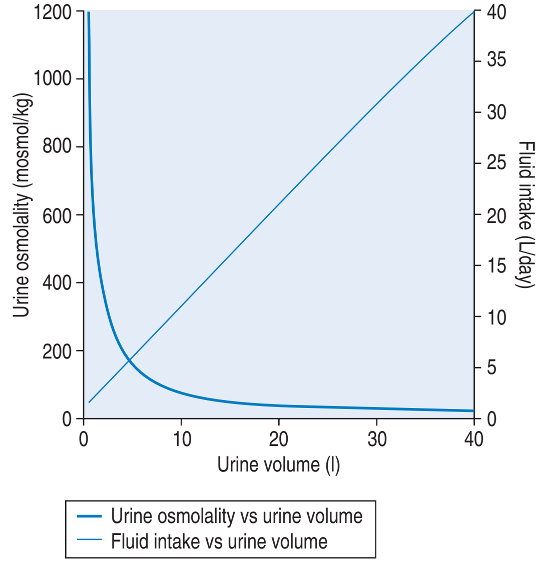

Figure 59.1 Urine output rises and urine osmolality falls in health as a function of increasing water intake. Assuming normal solute ingestion, normal solute excretion (around 800 mmol/day) is preserved between water intakes of 1.5 and 32 litres/day.

of water between itself and another fluid compartment. It may be considered an index of the water concentration rather than the solute concentration as the solute is impermeant. The tonicity of plasma is largely determined by its sodium content; the main solute in extracellular fluid that is not freely permeable to cross into the intracellular space. This characteristic facilitates the control of extracellular fluid volume through the regulation of sodium balance.

It is possible for a solution to be both hypotonic and iso-osmolar. Dextrose solution 5% is an example of this; the solution contains no impermeant solute (assuming no absence of insulin, glucose freely enters the cell) but is iso-osmolar with the intracellular milieu.

SOLUTE AND WATER INTAKE AND LOSSES

Assuming a normal diet, in a 75 kg man there is every day an obligatory loss of around 800 mmol of solute: approximately 300 mmol of urea and 500 mmol of cations and anions. The maximum concentrating ability of the healthy kidney is around 1200 mOsm/kg; consequently, a minimum of 666 mL of urine a day is required to excrete osmotically active solutes. Additionally, insensible losses of water (respiratory water, faecal water and sweat) approximate 10 mL/kg/day and this rises markedly with fever and hot dry climates. Thus, obligatory water losses of around 1.5 litres per day arise owing to insensible losses and obligatory solute excretion.

NORMAL URINARY OSMOLALITY

In health, urinary osmolality is usually maintained between 500 and 700 mOsm/kg. As the obligatory solute load to be excreted is relatively constant in value, urine osmolality will fall in response to an increased intake in free water and rise in response to dehydration or water restriction (**Fig. 59.1**). The minimum osmolality of urine achievable in man is around 25 mOsm/kg. Diuresis refers to the passage of a high volume of urine (>1.5 mL/kg/h) and may be transient or persistent, physiological or pathological. The production of >3 L/day is arbitrarily defined as polyuria. Water diuresis occurs when the total solute in the urine excreted per day is within the normal range but the osmolality of the urine passed is low. An osmotic or solute diuresis occurs when the total solute passed per day is higher than normal; the urine passed is usually iso-osmolar to plasma if the extracellular fluid volume is expanded or hyperosmolar if the patient is hypo- or euvolaemic.

PLASMA OSMOLALITY AND PLASMA VOLUME REGULATION

Changes in plasma osmolality and changes in plasma volume can occur in tandem or independently of one another. Whereas normal plasma osmolality lies in a population range of 275–295 mOsm/kg (270–280 mOsm/kg in pregnancy), individuals tend to vary less than ±1% around their set value. In pregnancy this

set value falls but the limited variability around it does not. The body regulates osmolality and volume by separate mechanisms. Water balance and osmolality are maintained via osmoreceptors, which mediate their control via control of thirst and ADH production.

Control of the plasma volume is maintained via volume receptors and sodium receptors, which mediate their actions through the sympathetic nervous system and the renin–angiotensin–aldosterone system. Additionally, the volume receptors have inputs to the hypothalamus via which they too can mediate ADH release and the sensation of thirst. Atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP), predominantly released from atrial and ventricular myocytes respectively, inhibit the release of renin, aldosterone, vasopressin and endothelin leading to both a natriuresis and a diuresis.[4]

THIRST

In health fluid intake is determined by the sensation of thirst and the subsequent ingestion of fluid. A plasma osmolality of >290 mOsm/kg, elevated angiotensin II (AII) concentrations, sympathetic nervous system activation and circulating volume depletion of 5–10% are all associated with the onset of thirst. Fluid and solute excretion are largely regulated through the kidney, although some solutes such as ethanol and glucose are largely cleared through metabolism rather than excretion.

In the ICU, the patient loses control over intake of fluids and solute and frequently has impaired excretory mechanisms. Thus both volume and solute homeostasis may become heavily dependent upon the skills of attending clinicians.

OSMORECEPTORS AND OTHER INPUTS TO THE SUPRAOPTIC AND PARAVENTRICULAR NUCLEI

Detection of osmolality occurs largely at osmo- (Na^+) receptors sited around the anterior aspect of the third ventricle of the brain. These are sensitive to plasma osmolality and CSF sodium concentration. Hypertonic saline is a more potent stimulus than equi-isotonic equi-ososmolar solutions of other solutes.[5] These osmoreceptors link to the cells of the paraventricular nuclei (PVN) and supraoptic nuclei (SON), the sites of ADH synthesis. The axons of the cells in the PVN and SON form part of the pituitary stalk linking the hypothalamus to the pituitary gland, in which they terminate. A smaller proportion of the axons terminate in the median eminence where they release ADH and oxytocin, which is transported to the anterior lobe of the pituitary by portal vessels. The ADH and oxytocin so released cause release of ACTH and prolactin respectively; the ADH acts synergistically with corticotropin-releasing factor (CRF) but is also believed to have ACTH secretagogue properties in its own right.[6,7]

Direct inputs from the sympathetic nervous system to the PVN and SON can stimulate ADH release via α-adrenoreceptors. Other central osmoreceptors lie outside the blood–brain barrier in the subfornical organ and come into contact with plasma. It is believed that ANP and AII[8] act via these receptors to inhibit or elicit ADH synthesis, ADH release and to modify the sensation of thirst. Additional osmoreceptors in the mouth, stomach, and liver are believed to play a role in the anticipation of an osmolal load following ingestion of food and pre-emptively can stimulate ADH synthesis in the hypothalamus.

As the baroreceptor and osmoreceptor inputs to the PVN and SON are distinct, it is possible to lose the normal ADH response to hyperosmolality but maintain a normal ADH response to hypovolaemia.[9] Additionally, in animal experiments, when hypotension increases the basal plasma ADH concentration, there is a simultaneous resetting of the osmomolality–plasma ADH response curve in an attempt to preserve osmoregulatory function from the new higher baseline.[10] If this did not occur, the ADH response to hypotension would always result in the development of a hypo-osmolal state in addition to causing vasoconstriction.

The normal response of osmoreceptors to changing plasma osmolality in terms of ADH is illustrated in Figure 59.2. At plasma osmolalities of <275 mOsm/kg, the osmoreceptors remain hyperpolarised and virtually no ADH release occurs via them. At osmolalities >295 mOsm/kg, the osmoreceptors are maximally depolarised and plasma concentrations of ADH of >5 pg/mL are attained. Other inputs and influences upon ADH release are summarised in Figure 59.3 and Box 59.2.

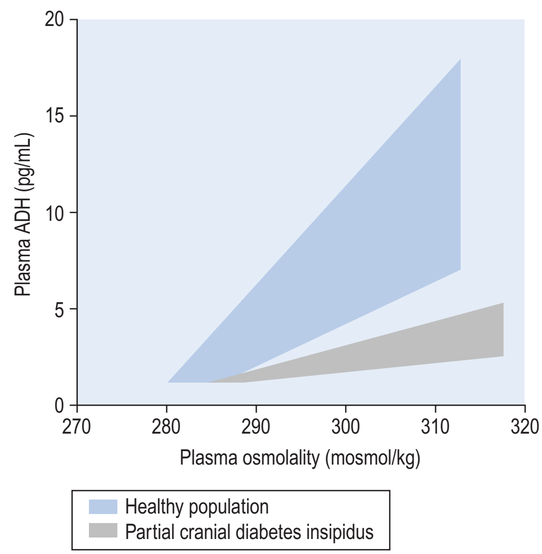

Figure 59.2 Plasma antidiuretic hormone (ADH) and plasma osmolality in health and partial cranial diabetes insipidus.

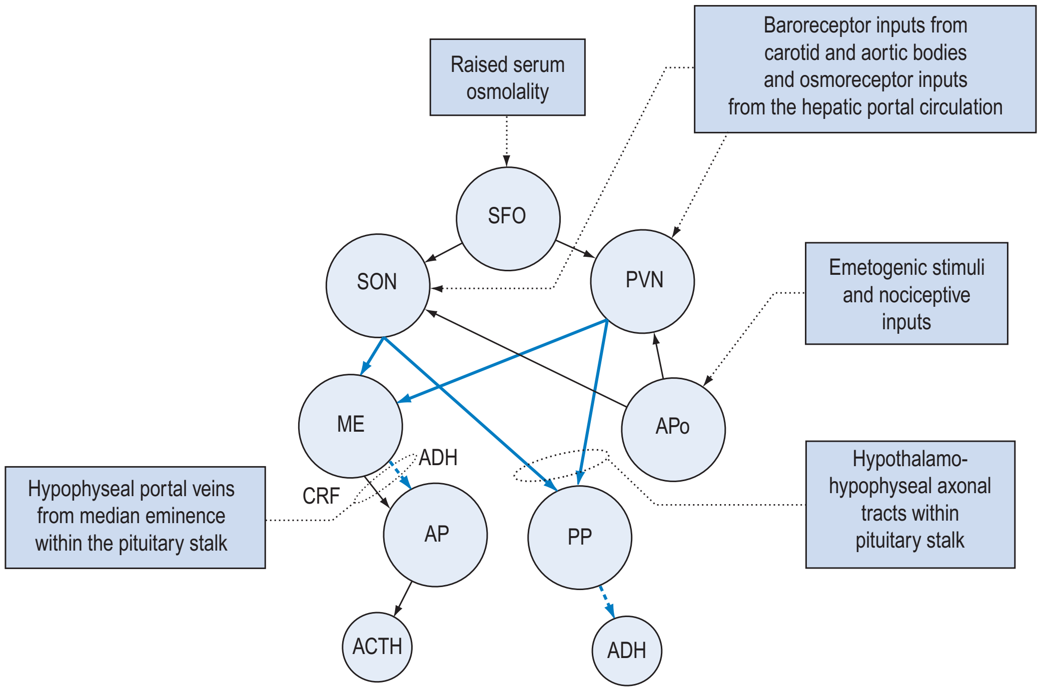

Figure 59.3 A schematic representation of anatomical and physiological connections of the supraoptic and paraventricular nuclei (SON and PVN), the principal sites of antidiuretic hormone (ADH) synthesis within the hypothalamus. Blue arrows represent the transport of ADH or its precursor between anatomically distinct sites. Baroreceptor inputs into these nuclei travel via the vagus nerve to reach the central nervous system. Whereas the majority of ADH produced in the SON and PVN is transported to the posterior pituitary (PP) for storage, some is transported to the median eminence (ME) then onwards to the anterior pituitary (AP), where it acts synergistically as a secretagogue for adrenocorticotropic hormone (ACTH). APo=area postrema; SFO=subfornical organ; CRF=corticotropin-releasing factor.

ANTIDIURETIC HORMONE (ADH)/ARGININE VASOPRESSIN (AVP)

ADH (8-arginine vasopressin) is a nine amino acid peptide that differs from oxytocin at only two residues but shares the disulphide bond between the 1st and 6th ones. This similar structure and conformation results in some cross-reactivity at receptors and in function.[11] It is synthesised in the SON and PVN, bound to neurophysin, transferred through axons to the posterior pituitary gland and stored in granules prior to release. Synthesis to replace any released stores is a rapid process (1–2 hours from synthesis to storage) and patients with damage to the pituitary can achieve near-normal plasma concentrations of ADH, in terms of osmoregulatory function, via release of newly synthesised ADH via the axons terminating in the median eminence. However, the higher plasma concentrations associated with hypovolaemia cannot be achieved. Normal osmoregulatory plasma ADH concentrations are in the range of 1–8 pg/mL but rise as high as 40 pg/mL in hypovolaemic patients under the influence of the sympathetic nervous system, baroreceptor responses and AII.

Once released from the pituitary, ADH has a plasma half-life of around 10–35 minutes.[12] It is metabolised by hepatic, renal and placental vasopressinases and around 10% of the active hormone is excreted unchanged in the urine.

ACTIONS OF ADH

ADH has antidiuretic, vasopressor, haemostatic and ACTH secretagogue actions. Additionally, it has roles in memory, water permeability of the blood–brain

barrier, nociception, splenic contraction and thermoregulation. These actions are mediated through V_1, V_2 and V_3 receptors. It also has actions on the uterus and mammary tissue mediated through oxytocin receptors. Cardiac inotropic effects are reported to be mediated through purinergic P_2 receptors, but this remains controversial.[13] Animal studies give conflicting reports of both positive and negative inotropic effects and their receptor mediation.[14]

Antidiuresis

ADH binds to V_2 receptors on the basal membranes of the principal cells of the collecting duct and distal tubule. The activated receptor induces production of cAMP by adenylate cyclase and this in turn activates protein kinases, which effect the integration into the luminal membrane of vesicles containing aquaporin-2 highly selective water channels. The production of prostaglandin E_2 (PGE_2) inhibits cAMP production. PGE_2 synthesis is stimulated by the action of ADH on V_1 receptors on the luminal membrane of the collecting duct.[15] Thus, a form of autoregulatory limitation of the antidiuretic effect of ADH may exist. Hypokalaemia, lithium and hypercalcaemia also antagonise the renal actions of ADH.

ADH also increases the urinary concentrating ability of the kidney by increasing the expression of urea transport proteins in the collecting duct and reducing renal medullary blood flow (V_1 mediated) facilitating an increase in medullary interstitial hypertonicity. This hypertonicity additionally depends upon intact functioning of the ascending loop of Henle where sodium and chloride are reabsorbed without absorption of water at the same time. Interference with this process reduces the osmolal gradient between the collecting duct and the interstitium and reduces water absorption even in the presence of ADH and functioning aquaporin-2.

In low dose, administration of exogenous ADH may paradoxically cause a diuresis in patients with septic shock.[16] This may be due to increased renal perfusion pressure resulting in an increase in GFR.

Vasoconstriction

At higher concentrations (>40 pg/cm), ADH activates not only V_2 receptors but also V_1 receptors through which it causes preferential vasoconstriction in muscle, skin and fat with relative sparing of coronary, cerebral and mesenteric circulations. However, these relative sparing effects are controversial, with some authors reporting relative sparing and others reporting significant vasoconstriction.[17–20] Activation of V_1 receptors activates phospholipase C and increases inositol triphosphate intracellularly. Ultimately this increases intracellular free calcium and leads to smooth muscle constriction in the blood vessel wall.

In brain-dead organ donors, a failure to produce ADH may result in the development of both hypotension and cranial diabetes insipidus with disturbances of osmolality and organ function. Treatment with α-adrenoceptor agonists may restore organ perfusion pressure but also cause ischaemic damage. The use of low-dose ADH infusions at 0.5–3 U/h titrated against urine output reduces the need for catecholamine support and also reduces perturbations in plasma osmolality and fluid balance; 1-deamino-8-*O*-arginine vasopressin (DDAVP) has similar benefits but causes less vasoconstriction. It is preferred for the treatment of cranial diabetes insipidus associated with brainstem death where hypotension is not a concomitant feature.

Coagulation

ADH increases circulating levels of tissue plasminogen activator, factor VIII and von Willebrand factor.[21] These effects may be mediated by V_2 receptors but this remains controversial. At high but physiological concentrations it can act as a platelet -aggregating agent.[22,23] Platelet aggregation is mediated through activation of platelet V_1 receptors.[24] ADH and its synthetic analogue DDAVP are used as first-line treatments in patients with von Willebrand's disease, and may be used in bleeding associated with renal failure and platelet dysfunction.

ACTH secretion

ADH transported via the portal venous system between the median eminence and the anterior pituitary acts upon V_3 receptors in the anterior pituitary to stimulate release of ACTH, which in turn increases plasma cortisol. The ADH both increases the efficacy of CRF in releasing ACTH and also has independent efficacy in stimulating ACTH release itself. In septic shock, it is possible that ADH insufficiency partially accounts for the relative adrenal insufficiency noted in certain patients. The relative importance and potency of ADH compared with CRF in stimulating ACTH release in humans is unclear.

VOLUME RECEPTORS

Volume homeostasis takes precedence over sodium homeostasis and so rises and falls in sodium will occur in order to preserve the circulating volume. In euvolaemic patients, sodium homeostasis is maintained. Sodium concentration is detected by both the osmoreceptors of the SFO outside the blood–brain barrier and the juxtaglomerular apparatus, which secretes renin in response to reduced GFR and a lower sodium load in the tubule.[25] The predominant determinants of sodium balance, however, are the high-pressure baroreceptors in the pulmonary veins, left atrium, carotid sinus and aortic arch.[26] Reduced stretch of these receptors increases sympathetic nervous system activity and activation of the renin–angiotensin–aldosterone system, resulting in reduced sodium excretion (via reduced GFR) and increased reabsorption of sodium in the proximal and distal convoluted tubules. Additionally, release of ADH can be stimulated resulting in

concomitant water retention. Conversely, stretch of the baroreceptors will result in a fall in sodium retention through reduced activity of the sympathetic nervous and renin–angiotensin–aldosterone systems. Stretch additionally results in the release of ANP/BNP and a natriuresis through reduced sodium reabsorption in the distal convoluted tubule and collecting duct. ADH release is reduced by the fall in sympathetic nervous tone from the baroreceptors. ADH secretion may also be inhibited by the action of ANP on cerebral osmoreceptors lying outside the blood–brain barrier.[27]

The role of low-pressure baroreceptors in the systemic venous circulation and right atrium is less clearly defined. When venodilatation occurs, as is seen in sepsis or when there is a reduction in cardiac output, reduced baroreceptor signalling in the high-pressure system will result in both sodium and water retention as outlined previously. This will expand the extracellular fluid compartment and potentially cause tissue oedema. As sepsis resolves, venous tone is restored, capillary leak reduces, an increase in the loading of the high-pressure baroreceptors results and a natriuresis takes place. Patients may become transiently polyuric as they clear the excess salt and water accumulated whilst shocked. During this physiological diuresis, plasma osmolality remains tightly within the normal range provided that renal concentrating mechanisms have not been injured during the septic episode or by drug administration.

CRANIAL DIABETES INSIPIDUS (CDI)

CONGENTIAL CDI

Congenital CDI is rare and usually inherited as an autosomal dominant characteristic that results from mutations of the gene encoding an ADH precursor – preprovasopressin neurophysin II.[28] The onset of the disease may occur anywhere between 1 year of age and middle adult life and is associated with the final destruction of the ADH-producing cells due to an accumulation of the abnormal ADH precursor.[29] Until the destruction of the SON and PVN cells occurs, ADH secretion (facilitated by expression of the normal gene) and regulation of plasma osmolality are often unaffected.

ACQUIRED CDI

Acquired CDI may be transient or permanent and can arise from an absolute (complete) or relative (incomplete) lack of ADH. Complete central DI is usually associated with lesions above the level of the median eminence, in the supraoptic or paraventricular nuclei or of the neurohypophyseal stalk whereby the production of ADH in the hypothalamus is terminated.[30] Permanent central DI tends to be associated with transecting, obliterating or chronic inflammatory lesions, whereas transient DI is more likely to be associated with acute inflammatory or oedematous lesions with some recovery of ADH secretion occurring as the inflammation or oedema resolves. An exception to this is the transient DI seen following excision or destruction of the posterior pituitary; ADH produced in the hypothalamus can still be released into the systemic circulation from capillaries in the median eminence. In the past the majority of acquired non-traumatic CDI was categorised as idiopathic but it has become apparent that the majority of these cases are associated with abnormality of the inferior hypophyseal arterial system[31] or autoimmune reactivity against ADH-producing cells.[32] However, association does not necessitate causality.

When the normal release of ADH into the circulation in response to rising plasma osmolality is reduced or absent, inappropriately high urine volumes are passed and the urine osmolality becomes inappropriately low for the state of water depletion being suffered by the patient. Where ADH is entirely absent from the circulation, over 20 litres of very dilute urine (25–200 mOsm/kg) per day may be produced. If the patient is unable to drink freely (most ICU patients), or the thirst mechanisms are impaired, profound dehydration will result very rapidly unless appropriate interventions are made by the physician. Where ADH deficiency is relative rather than absolute, it is possible for the patient to partially concentrate the urine and values of 500–800 mOsm/kg would not be atypical. However, these osmolalities are inappropriately low relative to the plasma osmolality. In partial ADH deficiency, volumes of urine as low as 3 litres per day may be evidenced. These are still inappropriately high when assessed in terms of the solute excretion of the patient, but are more difficult to recognise as being due to DI as there are many other causes of diureses of this magnitude. Additionally, extrinsic stimulants of ADH release (see Box 59.2) may have an antidiuretic effect further complicating the diagnosis.

The plasma osmolality measured in central DI is usually in the higher regions of the normal range or very slightly supranormal. It is remarkably constant in those with free access to water and intact thirst mechanisms as they will drink huge quantities of water to regulate and maintain their water balance. Hyperosmolality or hypernatraemia suggests impaired sensation of thirst or inability to access water (see water deprivation test later) and can also be seen if patients are administered large quantities of isotonic saline or Hartman's solution to replace their hypotonic urine losses. If unrecognised and untreated, hyperosmolality and hypernatraemia may result in death.

Cranial diabetes insipidus is usually associated with reduced production of ADH or damage to the normal release mechanisms of ADH. However, there can be dysfunction of the osmolality sensing mechanism at receptor or intracellular signalling levels whilst actual

Box 59.3 Causes of cranial DI

Acquired:
Idiopathic
Autoimmune
Tumours (especially suprasellar, lung, breast, lymphoma and leukaemia)
Surgery (especially trans-sphenoidal surgery)
Traumatic head injury (strongly associated with base of skull fracture[82])
Hypoxic brain injury
Brainstem death
Electrolyte disturbance – profound hyponatraemia
Radiotherapy
Drugs – amiodarone, lithium (Li more likely to cause nephrogenic DI)
Inflammatory/infectious diseases – sickle cell disease, tuberculosis, abscesses, encephalitis, meningitis, sarcoidosis (may also cause nephrogenic DI), Wegner's granulomatosis, histiocytosis X
Vascular disease – ischaemic or haemorrhagic strokes, aneurysmal bleeds (especially anterior communicating artery SAH), Sheehan syndrome, pituitary apoplexy

Congenital (1–2% of all cases)
Autosomal dominant mutations of ADH expression (despite the dominant expression of the gene, the onset of clinical DI may take up to 30 years to develop)[34]
Wolfram syndrome – autosomal recessive condition characterised by DI, diabetes mellitus, optic atrophy and deafness

ADH production and storage are normal. It is possible to have a normal release of ADH in response to baroreceptor detection of hypotension but subnormal release in response to hyperosmolality. This has been described in association with chronic hypernatraemia.[33]

The main recognised causes of central DI are listed in **Box 59.3**. A particularly common cause of DI seen in the ICU is traumatic or post-surgical brain injury. Trans-sphenoidal surgery for treatment of suprasellar tumours can result in DI in between 10 and 70% of patients; the frequency parallels the magnitude of the tumour being removed. Additionally, transcranial surgery may cause the development of DI in the absence of a fall in plasma ADH. This is postulated to be due to the release of a hypothalamic ADH precursor that acts as a competitive antagonist of both ADH and synthetic analogues. The presence of a competitive antagonist effectively creates an endocrinological picture similar to nephrogenic DI with normal or high plasma ADH levels but an inappropriate diuresis of dilute urine.

Following surgery or traumatic brain injury, several different patterns of polyuria can be seen. Immediate polyuria is common and may be transient or permanent. Occasionally it is preceded by a period of oliguria due to an initial surge of ADH release. Additionally, a classical triphasic pattern of urine output may be observed with: (i) transient polyuria due to transient impairment of the release of ADH (0–5 days in duration), then (ii) a phase of normal or reduced urine output – the ADH previously stored in the pituitary gland is gradually released into the circulation as the cells storing it involute (3–6 days in duration), and finally (iii) persistent polyuria as the pituitary stores exhaust and no replacement hormone from the hypothalamus is produced. During the second phase of this pattern, administration of fluids may result in volume overload and hyponatraemia as the ADH release is not under feedback control from osmoreceptors but occurs in an uncontrolled manner as a result of pituitary degeneration. Effectively, there is a transient syndrome of inappropriate ADH (SIADH) secretion. The triphasic pattern is usually associated with sudden severe damage to the hypothalamus or pituitary from trauma, surgery or intracranial bleed, and careful, regular clinical and biochemical assessment is essential to ensure normal water balance and osmolality during this transition from DI to SIADH and back to DI again.

The exact nature of the urinary pattern seen in DI is relatively unimportant and gradual resolution may occur over several months in those with transient DI. Imaging the hypothalamus and pituitary with T1 MRI may provide prognostic information as to whether recovery is likely or not; hypothalamic lesions have a poorer prognosis than pituitary ones.[35] What is essential is that meticulous assessments of the patient and their plasma and urinary biochemistry as well as fluid inputs and outputs are made to prevent the development of unnecessary fluid and solute imbalances that could lead to worsening morbidity or mortality. It is important to maintain a high level of suspicion for the development of DI in anyone who is suffering from pituitary disease or who has suffered a pituitary injury as the symptoms may have gradual onset. Anterior pituitary failure can lessen the impact of central DI because of the deficiency of ACTH and cortisol, which reduces GFR and free water loss. Additionally, the loss of feedback inhibition may stimulate increased release of ADH from the median eminence. Thus, in Sheehan's syndrome and pituitary apoplexy, the presenting symptoms tend not to be those of DI with polyuria. However, once corticosteroid therapy is commenced then polyuria indicating DI may become apparent or exacerbated. Conversely, patients with persistent DI of idiopathic origin should have long-term endocrine follow-up as a number will go on to develop tumours of the pituitary several years after the diagnosis of DI.[36,37]

TREATMENT OF CDI

Four separate problems have to be addressed when treating CDI:

1. Associated anterior pituitary dysfunction should be considered and managed when present.
2. Hypernatraemia must be recognised and treated with painstaking care.

3. Any deficit of total body water must be recognised and addressed (this may be urgent if the patient is shocked).
4. The underlying deficiency of ADH causing the polyuria must be addressed.

In all ICU patients with DI, hourly urine measurements, hourly fluid losses and fluid inputs and at least twice-daily urine and plasma osmolalities are recommended. In shocked patients and those with hypernatraemia, hourly monitoring of plasma sodium is recommended to prevent worsening of hyperosmolality or over-rapid correction of hypernatraemia.

ANTERIOR PITUITARY DYSFUNCTION

If this is present, it requires recognition and treatment. In the emergent situation with a shocked patient, hydrocortisone 100 mg can be administered as an i.v. bolus, and steroid replacement continued if needed. Steroid administration may worsen the diuresis but will improve cardiovascular stability in patients with pituitary ablation.

HYPERNATRAEMIA

If the patient with CDI and ongoing water diuresis has had restricted access to fluids and developed hyperosmolality/hypertonicity, or has developed hypertonicity through replacement of dilute urine with equal volumes of isotonic (to plasma) intravenous fluids, then sudden reduction in plasma tonicity may result in cerebral oedema, pontine myelonecrosis and permanent neurological damage as a result of water moving into brain cells down an osmotic gradient (see below). In order to counteract cellular dehydration in chronic (>24 hours) hypernatraemic states, the brain accumulates intracellular organic osmolytes such as amino acids, taurine and sorbitol.[38–40]

When a euvolaemic state is present, arginine vasopressin or DDAVP may be administered to reduce urine output (see below). At the same time, fluid restriction should be imposed and replacement of the previous hour's urine output undertaken with an appropriate fluid to avoid a fall in concentration of sodium by more than 0.5 mmol/h.[41] Absolute safety data are not available to determine the ideal rate of reduction of plasma sodium. However, when a patient has been hypernatraemic for more than 48 hours, a fall of more than 8 mmol/L in any 24-hour period should be avoided.[42] Several formulae exist to guide fluid replacement regimens controlling the rate of fall of plasma sodium concentrations; reliance on these is not recommended and extremely close monitoring with hourly review of plasma sodium is less likely to result in sudden unexpected changes in tonicity.[43]

DEHYDRATION AND HYPOVOLAEMIA

If associated with shock, hypovolaemia requires rapid resuscitation. If hypovolaemia is also associated with hypernatraemia, extreme caution is required in the resuscitation, which should take place with isotonic saline solution and frequent reassessments of plasma sodium and cardiovascular and neurological status. Where the hypernatraemia is very marked (>155 mmol/L), consideration of a combination of isotonic (0.9%) and hypertonic saline should be given to reduce the rate of sodium reduction. In the face of hypertonicity of the plasma, cells reduce their chloride and potassium conductance in addition to synthesising intracellular osmolytes. If 0.9% saline (effective osmolality 290 mOsm/kg when diluted by plasma proteins) is infused rapidly into hypertonic plasma with a sodium of 160 mmol/L, an effective osmolality of 330 mOsm/kg, a rapid drop in plasma osmolality may cause cerebral and other organ oedema, seizures and death. By reducing the tonicity of the plasma gradually, the cells have time to down-regulate their synthesis of intracellular osmolytes and increase potassium and chloride conductance to reduce swelling as plasma tonicity falls.

CORRECTION OF POLYURIA AND ADH DEFICIENCY

At mild levels of polyuria (2–3 mL/kg/h) where there is an expectation that the condition may resolve, it may be appropriate to merely replace the previous hours' urine output with an appropriate fluid (usually 5% dextrose or 0.18% saline/4% dextrose) whilst undertaking regular measurements of plasma and urine osmolality and electrolytes. Care must be taken not to give so much dextrose as to result in hyperglycaemia, hyperosmolality and osmotic diuresis.

Where polyuria is expected to be persistent or is excessive, either ADH/AVP or DDAVP may be administered. DDAVP is a selective V_2 receptor agonist and thus is less likely to cause hypertension. It is also longer acting, resisting breakdown by vasopressinases, and is usually administered once or twice daily. The usual daily dose rate, when administered intravenously, intramuscularly or subcutaneously is 1–4 μg daily. ADH may be administered subcutaneously or by intravenous infusion and DDAVP may be presented intranasally, subcutaneously, intravenously or orally. In the acute situation, an ADH infusion (0.1–3 U/h) can be conveniently titrated against urine output. The use of the infusion ensures 100% bioavailability and facilitates re-establishment of the hypertonic renal medullary interstitium before changing the patient to the longer acting DDAVP. The dose of ADH or DDAVP is often higher during the acute onset phase of CDI – this may be due to the loss of hypertonicity in the medullary interstitium or due to biologically inactive ADH precursors released from the damaged hypothalamic–pituitary tract, which act as competitive antagonists at the V_2 renal receptors. The dose of ADH or DDAVP used is the minimum dose required to control urine output to an acceptable rate. Excessive administration can result in water retention and the development of hypo-osmolal syndromes.

Other drugs may also be used to reduce the polyuria of CDI. Provided there is some residual ADH synthesis, chlorpropamide, clofibrate and carbamazepine are all reported to enhance ADH release and also increase the renal responsiveness to ADH. Thiazide diuretics may also be effective. Although these agents all reduce urine output, there is little place for them in the modern management of CDI in the ICU where DDAVP and ADH have excellent safety profiles and are more easily titrated to effect. These alternative drugs are discussed later in the treatment of nephrogenic DI.

NEPHROGENIC DIABETES INSIPIDUS

Nephrogenic diabetes insipidus (NDI) may be congenital or acquired (**Box 59.4**). As the majority of congenital cases present in the first week of life, the majority of cases seen in the adult ICU are acquired. The commonest of these are lithium toxicity due to long-term drug treatment, hypercalcaemia and post-obstructive uropathy following relief of ureteric or urethral obstruction.

CONGENITAL NDI

Some 80–90% of patients with congenital NDI have an X-linked recessive abnormality of the $AVPR_2$ gene coding for the V_2-receptor.[28,44] Different mutations of the gene are described but the majority result in trapping of the V_2-receptor intracellularly, and unable to integrate into the membrane of the collecting duct cell. Drugs have been developed that can facilitate receptor integration into the membrane, restoring some of the urine-concentrating abilities of ADH.[45] The sex linkage results in the vast majority of affected patients being male. However, female children can also present less severe polyuria and polydipsia due to expression of the abnormal gene. Non-sex-linked genetic abnormalities can also cause NDI. Approximately 10% of cases of congenital NDI have mutations of the AQP_2 (aquaporin 2) gene, which codes for the AQP_2 channel. Over 40 mutations, both autosomal dominant and recessive, have been described to date.

The remainder of cases of congenital NDI arises from a variety of pathophysiologies that result in failure to generate a hypertonic renal medulla, with inability to reabsorb water even if the V_2 receptor and acquaporin$_2$ channels are normal. A lack of the Kidd antigen (a blood group antigen) results in an inability to concentrate urine to more than 800 mOsm/kg even with water deprivation and exogenous ADH administration.[46] This is because the antigen is also expressed in the collecting duct epithelium where it functions as a urea transporter (urea transport B protein) and facilitates movement of urea from urine into the medullary interstitium maintaining some of the gradients required to facilitate water reabsorption. Similarly, patients with mutations in chloride channel genes, potassium channel genes or the sodium–potassium–chloride co-transporter gene resulting in the Bartter syndrome are unable to generate a hypertonic medullary interstitium. However, in these patients the defect is more marked and urine can rarely be concentrated above 350 mOsm/kg.[47]

With congenital NDI, early diagnosis and management are essential as avoidance of hypernatraemia and dehydration facilitate the achievement of normal developmental milestones and avoid the cerebral damage once commonly accepted as an inevitable association of NDI.

Box 59.4 Causes of nephrogenic DI

Acquired	Congenital
Lithium toxicity	X-linked recessive: $AVPR_2$ gene mutations
Postobstructive diuresis	Autosomal recessive or dominant: AQP_2 gene mutations
Hypercalcaemia	Bartter syndrome
Hypokalaemia	Gitelman syndrome
Hypoproteinaemia	Urea transport protein B (Kidd Ag) deficiency/absence
Sjögren's syndrome	
Amyloid	
Multiple myeloma	
Sickle cell disease	
Polycystic kidney disease	
Pyelonephritis	
Renal transplantation	
Other drugs: amiodarone, amphotericin B, clozapine, colchicine, demeclocycline, foscarnet, gentamicin, loop diuretics, rifampicin	

ACQUIRED NDI

Lithium-associated nephrotoxicity remains the commonest form of acquired NDI with more than 20% of patients on chronic lithium therapy developing polyuria. Lithium is taken up into the principal cells of the collecting duct via sodium channels and inhibits intracellular adenylate cyclase, antagonising the effects of ADH. Additionally, it reduces the medullary interstitial hypertonicity possibly through reducing expression of urea transport protein B. If patients with early lithium-related NDI are prescribed amiloride, some reversal of both the polyuria and lithium mediated toxicity is possible. Amiloride's natriuretic action is achieved through closure of the luminal sodium channels in the collecting duct, the sodium channels through which lithium enters the cells.[48] Indomethacin increases intracellular cAMP and counteracts the diminution of this and AQP_2 caused by lithium, resulting in a marked and immediate drop in urine output. However, care is required as NSAIDs may worsen renal failure, reducing GFR and lithium excretion thereby worsening toxicity.

Hypercalcaemia, hypokalaemia, release of ureteric or urethral obstruction and hypoproteinaemia are also

recognised as causing NDI and are associated with reduced expression of AQP_2 channels, urea transport proteins and a loss of interstitial hypertonicity. These defects normally cause milder polyuria than that associated with lithium toxicity. Finally, the attritions of ageing lead to loss of urinary concentrating ability. It is suggested that this is due to a combination of pathophysiological changes characteristic of both NDI and CDI with relative reductions of both AQP_2 and AVP production.[49]

TREATMENT OF NDI

The treatment of NDI aims to minimise the occurrence of hypernatraemia and hypovolaemia and wherever possible to remove the underlying cause.

1. *Correct reversible causes:* stop any drugs suspected in the aetiology; then correct hypokalaemia, hypercalcaemia and hypoproteinaemia.
2. *Reduce solute load:* as urine output is determined by the solute load to be excreted, reducing the solute intake will reduce the urine volume accordingly; if maximum urine concentration is 250 mOsm/kg, a solute intake of 750 mOsm day requires production of at least 3 litres of urine to clear the solute, whereas if intake is reduced to 500 mmol then 2 litres of urine will suffice. In ICU, the reduction of solute can be difficult as many drugs and diluents have a high solute load. Additionally, patients may be catabolic and have a high protein requirement. It may be more appropriate not to aim to restrict solute intake for certain patients but to monitor fluid balance closely and ensure adequate appropriate replacement:
   a. Restrict salt intake (aiming at <100 mmol/day)
   b. Reduce protein intake aiming to provide the minimum daily requirement including essential amino acids. This should be done with specialist dietetic advice and requires careful follow-up to avoid protein malnutrition. It is not appropriate to protein-restrict children where it may adversely affect normal growth and development)
3. *Diuretics – thiazides and amiloride:*
   a. Thiazides – whereas DI loses water in excess to solute rendering the plasma hyperosmolal, resulting in intracellular dehydration to maintain the intravascular volume, thiazide diuretics cause solute loss in excess of water and lead to a drop in intravascular volume. This causes activation of the sympathetic nervous system and the renin–angiotensin–aldosterone system and a fall in glomerular filtration and ANP. Additionally, thiazides are associated with an increased expression of AQP_2 channels in the collecting duct.[50] These neuroendocrine changes lead to an increase in proximal tubular reabsorption of sodium and water and an increase in ADH release. Less ultrafiltrate reaches the collecting duct and urine volume can fall by as much as 30%. Combined with a solute-reduced diet, the fall in urine production can be as high as 50%.
   b. Amiloride is a useful adjunct to thiazide diuretics in NDI where it causes a further slight reduction in urine output and combats the hypokalaemia associated with the thiazides. It may have benefit in its own right in lithium-associated nephrotoxicity where it blocks the sodium channels through which lithium enters the principal cells. If administered before lithium damage becomes irreversible, it can both reduce the damage to the cells themselves and reverse the antagonism of lithium on the effects of ADH.

   Loop diuretics are not effective in reducing the diuresis of NDI as, whilst they reduce intravascular volume and stimulate the sympathetic nervous system in a similar manner to thiazides, they also reduce interstitial medullary sodium concentrations and hypertonicity thus reducing water reabsorption by the collecting duct rather than enhancing it.
4. *ADH:* where NDI is not absolute (most cases of acquired NDI), supplementing endogenous ADH to create supraphysiological concentrations in the plasma can result in a fall of urine production by up to 25%. This may occur by antagonism of the effects of any V_2 receptor antagonists present or through greater receptor occupation. Care is required with long-term use as hypertension and its associated complications may result.
5. *NSAIDs:* PGE_2 increases GFR and urine flow and decreases intracellular cAMP and thus aquaporin expression. NSAIDs reduce the formation of renal PGE_2 and when used alone may reduce urine output by up to 50%.[51] Combination with low-solute diet and a thiazide diuretic may provide additional antidiuretic benefit.[52] However, the use of NSAIDs has to be weighed against their long-term complications. This is particularly true in the ICU population who are at increased risk of both renal impairment and gastric erosions. Indomethacin is cited to have greater treatment benefit than other NSAIDs in NDI.[53] It is also more likely to produce unwanted adverse effects.
6. *Chlorpropamide:* this oral hypoglycaemic agent enhances both ADH release and the sensitivity of the kidney to it. It is suggested to act via increasing the hypertonicity of the renal medulla. Doses of 250 mg o.d. or b.d. are prescribed, but are likely to cause hypoglycaemia.[54] Its use is therefore reserved for severe refractory cases of partial NDI.
7. *Clofibrate:* this oral lipid-lowering agent is reported to enhance ADH release and increase the renal sensitivity to ADH.[55] Its use in CDI has largely been superseded by the introduction of safer, more efficacious DDAVP therapy. Its use in treatment of DI has been associated with myopathy.[56] If considered for

treatment of partial NDI, biochemical markers of myopathy should be measured regularly.

8. *Carbamazepine:* carbamazepine can also be tried as a treatment in partial NDI although it is more effective in treating partial CDI. It increases the renal responsiveness to ADH, but requires a dose rate three times higher than that effective as an antiepileptic. This high dose rate limits its usefulness in therapy.
9. *Molecular chaperones:* novel drugs described as 'molecular chaperones' are being developed to treat NDI where the V_2 receptor is functional and intact but confined to the intracellular space, unable to integrate into the basolateral membrane of the principal cell.[57] The drugs are membrane-permeable V_2 receptor antagonists and are believed to cause refolding of the receptor in a form that allows normal processing of the receptor into the membrane.[58] These are showing some success in animal models of congenital NDI and with human V_2R mutations associated with NDI in testing in vitro. Early studies in humans report some success.[59] Unfortunately, a recent study with Relcovaptan (SR49059), whilst showing very promising clinical results, had to be discontinued owing to possible interference in the cytochrome P450 pathway. Nevertheless, other chaperone molecules are currently being explored for human testing.[60]

GESTATIONAL DI (GDI) (Box 59.5)

In pregnancy the normal range of plasma osmolalities falls to 265–285 mOsm/kg and the plasma sodium is <140 mmol/L. The reduction in osmolality is attributed to a resetting of the central osmostat[61,62] with the onset of development of thirst at an osmolality around 10 mOsm/kg lower than in the non-pregnant state. This has been attributed to increases in the plasma concentration of human chorionic gonadotropin (hCG).[63] The retention of water and sodium is mediated by reduced baroreceptor stimulation.[64]

During pregnancy, the placenta produces vasopressinases (cysteine–aminopeptidases) that increase ADH metabolism up to fourfold[65] and relaxin, which contributes to the 50% increase in GFR and venodilatation.[66] Aldosterone concentrations rise up to fivefold. Solute elimination also increases; a small reduction in urine-concentrating ability may have a more marked effect. The volume of urine passed per day increases as a result of passage of an increased solute load (including urinary proteins, glucose and amino acids), increased drinking and a raised GFR. A diagnosis of DI therefore requires careful differentiation from a physiological polyuria or potentially pathological polyuria of separate aetiology (e.g. gestational diabetes) in pregnancy.

GDI occurs in around 1:300 000 pregnancies and can result from:

1. Increased destruction of ADH by excessive production of placental vasopressinases[67] (especially gemellar pregnancies) or reduced deactivation of vasopressinases (e.g. in acute fatty liver of pregnancy,[68] pre-eclampsia or HELLP syndrome) – this may be unresponsive to exogenous ADH administration as it too is rapidly metabolised. DDAVP can be used instead as it is resistant to degradation by placental vasopressinase.
2. Permanently deficient reserve of ADH secretion, which in the non-pregnant state is asymptomatic but in the pregnant state is unmasked by the higher vasopressinase activity that cannot be compensated for by increased secretion.[69] This condition responds to treatment with ADH/DDAVP and is indicative of latent, subclinical DI that predated pregnancy. Investigation and follow-up following pregnancy is warranted as a proportion of patients in this category will develop later hypothalamo–pituitary axis pathologies such as tumours or autoimmune hypophysitis.
3. Central DI associated with Sheehan syndrome and pituitary apoplexy – Sheehan syndrome is commonest, and is usually preceded by major bleeding or hypotension at the time of delivery. Pituitary apoplexy has been described antenatally too.[70]
4. Gestational nephrogenic DI of unknown aetiology that is resistant to both ADH and DDAVP, with resolution in the postnatal period.[71]

The treatment of GDI varies depending on the underlying cause. In all cases, it is important not to allow the patient to become hypernatraemic and hyperosmolal as this is likely to have adverse effects on both mother and child. Where hypernatraemia and hyperosmolality do occur, careful correction is required in a closely monitored, very gradual, stepwise fashion. A lowering of sodium by as little as 10 mmol/L per day has been associated with pontine myelinolysis.[72]

The associations between acute fatty liver of pregnancy, HELLP and pre-eclampsia and DI are well recognised, if not fully understood. It has been suggested that liver dysfunction results in reduced clearance of the vasopressinases released by the placenta and thus increased clearance of maternal ADH.[73,74] It is important to bear these associations in mind as the polyuria of

Box 59.5 Causes of gestational DI

Sheehan syndrome	Vasopressinase release by placenta
Pituitary apoplexy	Idiopathic gestational NDI (resolves post-partum)
Hepatic dysfunction: acute fatty liver of pregnancy, pre-eclampsia, HELLP syndrome	

DI may mask the hypertension and fluid overload of pre-eclampsia and HELLP leading to later diagnosis, delayed management and poorer outcome.[75]

POLYDIPSIA (PSYCHOGENIC/NEUROGENIC/PRIMARY)

Polydipsia may result from: (i) a psychiatric disorder or disturbance,[76] (ii) drugs that give the sensation of dry mouth[77] or airways to the patient (e.g. oxygen therapy, phenothiazines, anticholinergics), or (iii) hypothalamic lesions that directly disturb the thirst centre[78] (e.g. sarcoidosis). In all three of the above causes of polydipsia, excessive drinking is associated with the production of large quantities of urine of appropriate osmolality. If the fluid ingested is largely hypotonic, the urine will be hypo-osmolal and result from a fall in ADH secretion. If the fluid ingested is hypertonic, the urine will have high osmolality but remain of high volume because of the combination of low ADH production and high ANP production causing a solute diuresis.

Polydipsia may also result from the appropriate detection by osmoreceptors of a raised plasma osmolality due to raised glucose, alcohol or sodium. The glycosuria itself will cause an osmotic diuresis and plasma osmolality may be normal or raised depending on the severity of the hyperglycaemia and any accompanying ketoacidosis and dehydration.

Excessive drinking of hypotonic fluids leads to hyponatraemia and may progress to water intoxication with cerebral oedema, confusion, impaired consciousness, seizures and death. It has also been postulated that long-term polydipsia may lead to the development of dysregulation of ADH secretion and cranial DI.[79] These are important considerations in patients presenting with reduced consciousness and polyuria; water intoxication, more usually associated with SIADH, and DI may coexist.

SOLUTE DIURESIS

Just as failure to reabsorb water can result in polyuria, failure to reabsorb solute can result in an osmotic load in the tubule that opposes water absorption in the convoluted tubules and collecting duct. The commonest cause of this in the general patient population is glycosuria. In the ICU setting, a solute diuresis may also be associated with the administration of diuretic drugs, high-protein feeds (increased urea load), supranormal quantities of sodium and other solutes through fluids, feeds and drugs, recovery from acute renal failure with tubular inability to reabsorb solute, and drug-induced tubular damage.

To differentiate a solute diuresis from a water diuresis it is advisable to measure the 24-hour excretion of solute in the urine. Normally, between 600 and 900 mOsm/day of solute are excreted in the urine. Values higher than this indicate a solute diuresis. A spot urine osmolality may be measured; osmolality higher than 300 mOsm/kg, is suggestive of a solute diuresis. It would not be uncommon in the critically ill patient to encounter simultaneous impairment of both water reabsorption and impaired solute elimination. In this instance, 24-hour solute excretion will be increased but the urine may be hypo-osmolal.

THE DIAGNOSIS OF POLYURIC SYNDROMES

MEASURE AND CALCULATE PLASMA OSMOLALITY AND URINE OSMOLALITY

A high urine osmolality in the presence of a high plasma osmolality is appropriate and if the plasma osmolality is higher than 295 mOsm/L, urine osmolality should reach 1000–1200 mOsm/kg. Urine osmolalities of less than this imply that there is a urine-concentrating defect and lead to consideration of the causes of diabetes insipidus or medications that might reduce renal interstitial hypertonicity such as loop diuretics. Urine osmolalities of <150 mOsm/kg in this circumstance are sufficient to make the diagnosis of DI provided there is not obvious gross fluid and solute overload of the patient.

Where the patient is polyuric with a high plasma osmolality and maximum urine osmolalities are being achieved, an osmotic diuresis is implied. The diuresis may be inappropriate in as much as it is leading to dehydration, but appropriate in that the kidneys are retaining as much water as they can for the large solute load being excreted. If there is a normal *osmolal gap* (the difference between measured and calculated plasma osmolality, normal <10 mOsm/kg), hyperglycaemia, hypernatraemia or hyperkalaemia are implied. If the osmolal gap is greater than 10 mOsm/kg, investigation should be undertaken to look for an unmeasured solute such as ethanol, mannitol, ethylene glycol, sorbitol or methanol. If plasma osmolality is less than 280 mOsm/kg, urine osmolality would also be expected to be lower than this to clear free water. This picture implies water overload, which may be iatrogenic or patient mediated. Low plasma osmolality with high urine osmolality implies SIADH and would not normally be associated with polyuria.

WATER DEPRIVATION AND ADH TESTS

In health, being deprived of water rapidly results in an increase in plasma osmolality, which causes ADH release and an increase in urine osmolality to 1000–1200 mOsm/kg in order to preserve water and reduce plasma osmolality back towards its normal value. When the cause of polyuria is unclear and the

patient is not already clinically dehydrated, a water deprivation test may be useful to determine the cause of the diuresis. In patients with severe polyuria, the test is potentially dangerous as dehydration and hyperosmolality may develop very rapidly resulting in permanent cerebral damage and cardiovascular collapse. It is therefore necessary to undertake the test under very close supervision during daylight hours.

The limitations of the test should also be appreciated:

1. In acute CDI, release of ADH precursors from injured brain tissue may render interpretation of ADH tests unreliable through cross-reactions with ADH measurement assays.
2. At high concentrations of ADH, the urine concentrations achieved in partial NDI and primary polydipsia may be similar.
3. Patients with partial CDI may occasionally become hypersensitive to relatively small rises in ADH, which may be induced by the rise in osmolality associated with water deprivation and thus maximally concentrate urine once osmolality is raised leading to an erroneous diagnosis of primary polydipsia.[80]
4. In patients with chronic hypernatraemia and CDI secondary to osmoreceptor dysfunction, hypovolaemia with water deprivation may cause sufficient baroreceptor stimulus to release ADH and suggest normal urine concentrating abilities.[81]

Step 1: plasma and urine osmolalities, plasma ADH and patient body weight are measured at time zero and access to i.v./oral fluids is denied.

Step 2: plasma and urine osmolalities and patient body weight are measured hourly until either three consecutive urine osmolalities are within 30 mOsm/kg of one another or plasma osmolality is >295 mOsm/kg, or the patient loses more than 5% of the body weight from baseline. At this time, plasma ADH is measured again.

Step 3: if plasma osmolality is >295 mOsm/kg and urine osmolality is <800 mOsm/kg, ADH (5 units AVP s.c. or 4 µg DDAVP s.c.) is administered to the patient and plasma and urine osmolalities are measured hourly for 3 hours (this time is necessary to allow time for at least partial recovery of the medullary interstitial hypertonic gradient in patients with primary polydipsia). DDAVP is preferred to AVP as it avoids misinterpretation of results in the presence of vasopressinases, which would rapidly metabolise AVP and suggest a diagnosis of NDI rather than CDI. Although neither is the correct diagnosis if vasopressinases are present, the treatment is as for CDI (i.e. the administration of DDAVP).

Step 4: urine osmolality is then plotted against plasma osmolality (**Fig. 59.4**).

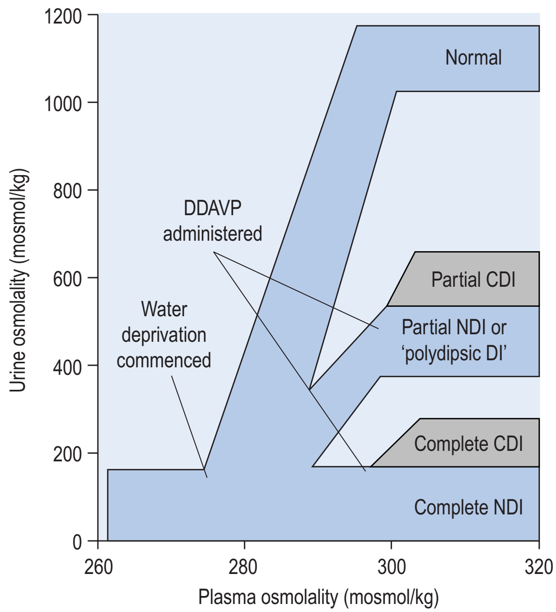

Figure 59.4 Urine versus plasma osmolality during water deprivation testing. DDAVP = 1-deamino-8-*O*-arginine vasopressin; CDI = cranial diabetes insipidus; NDI = nephrogenic diabetes insipidus. *(Adapted from Sands JM, Bichet DG. Nephrogenic diabetes insipidus. Ann Intern Med 2006;144:186–94.*[49]*)*

Step 5: plasma and urine osmolalities are plotted against plasma ADH concentrations (**Fig. 59.5**).

INTERPRETATION OF THE TESTS (SEE FIGS 59.4 AND 59.5)

In complete DI, plasma osmolality will rise but urine osmolality will not rise above 300 mOsm/kg. Upon administration of ADH, patients with complete CDI will raise their urine osmolality to 500 mOsm/kg or higher, whereas there will be no rise in urine osmolality in complete NDI. In complete CDI the original plasma ADH measurement will be zero, whereas in complete NDI the initial ADH measurement will be normal or high depending upon the corresponding plasma osmolality at the time of measurement. In partial DI, plasma osmolality will rise and urine osmolality will also increase but usually plateaus between 400 and 800 mOsm/kg. In partial CDI the ADH will initially be normal or low and will rise with increasing plasma osmolality but is unlikely to rise above 4–5 pg/mL. In partial NDI, the ADH will initially be normal or high and will increase with plasma osmolality to >8 pg/mL but without achieving a correspondingly appropriate rise in urine concentration.

Following administration of ADH or DDAVP, urine osmolality is expected to at least double in complete

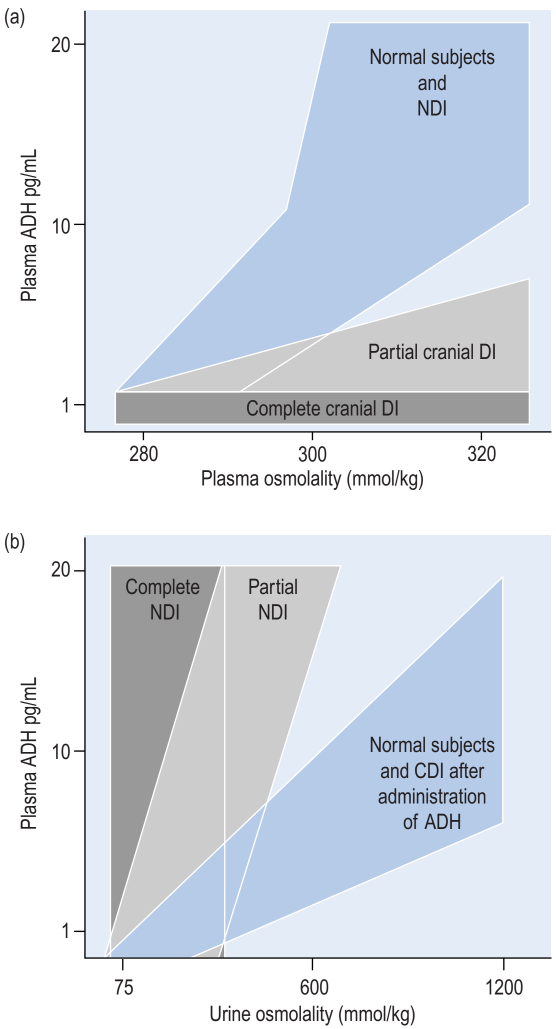

Figure 59.5 (a) As plasma osmolality increases as a result of water deprivation or hypertonic saline infusion, the measured concentration of antidiuretic hormone (ADH) should rise. Failure to do so suggests cranial diabetes insipidus. (b) At a given value of plasma ADH, whether endogenous or exogenous in origin, urine osmolality is expected to lie within a corresponding range of osmolality. However, the range of expected osmolalities is high as osmoreceptors adjust regulation around the basal level of ADH, which is also partly determined by volume receptors. In nephrogenic diabetes insipidus (NDI), the urine osmolality remains low even when high plasma ADH concentrations are measured.

CDI and rise by 10–50% in partial CDI or NDI. In complete NDI, there will be no rise in urine osmolality. Partial CDI may be inferentially differentiated from partial NDI on the basis of urine osmolality alone; in the former, urine osmolality rises above plasma osmolality whereas in partial NDI it tends to remain hypo-osmolal or iso-osmolal to plasma following ADH/DDAVP administration. However, this generalisation is indicative only and for greater certainty it is preferred to have measured sequential ADH concentrations to assess hypothalamic–pituitary function independently of the renal concentrating ability.

Water deprivation tests should not be conducted in infants, patients with pre-existing hypovolaemia or hyperosmolality. In the latter two categories, treatment of the fluid deficit and/or solute excess should precede further investigations. In infants and in adults with equivocal water deprivation test results, an infusion of hypertonic saline should be considered.

HYPERTONIC SALINE INFUSION TEST

In patients with equivocal results from a water deprivation test and in those at high risk of dehydration and hypovolaemia from water deprivation, a hypertonic saline infusion test may be undertaken to establish the cause of a water diuresis. Interpretation of the test is as for the water deprivation test, but there is a clearer demarcation between partial CDI and primary polydipsia (the latter having a normal rise in ADH in response to increasing plasma osmolality, whereas the former will have no rise or an obtunded one) and the risk of missing a diagnosis of CDI secondary to osmoreceptor dysfunction is reduced.[82]

Hypertonic saline is available in multiple different concentrations. Care is required in calculating the appropriate infusion rate to use for the test as this varies with the concentration of the hypertonic preparation stocked. 0.0425 mmol/kg/min of hypertonic sodium chloride solution is infused for up to 3 hours or until a plasma osmolality of 300 mOsm/kg is achieved.

Blood samples are taken 30 minutes before and at 30-minute intervals throughout the duration of the test and plasma sodium, osmolality and ADH are measured. Urine samples are collected before and where possible at 60-minute intervals throughout the test period and measurements of osmolality and sodium performed. Thirst and blood pressure are recorded at 30-minute intervals.

MRI-T-1-WEIGHTED IMAGING OF THE NEUROHYPOPHYSEAL TRACT

Imaging may be helpful in differentiating partial CDI from psychogenic polydipsia where results of a water deprivation test and the history make the differentiation uncertain. In CDI, the normal bright spot (stored ADH[34]) seen in the posterior pituitary is usually reduced or absent, whereas in psychogenic polydipsia it is usually well preserved or even enhanced (Fig. 59.6).

Although rapid and less labour intensive than a hypertonic saline infusion test, the results of MRI are not yet held to be entirely specific or sensitive. It is reported that the signal is often reduced in nephrogenic

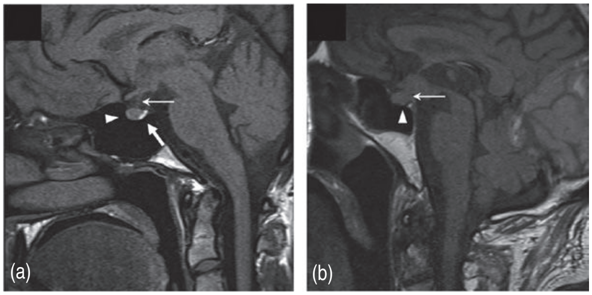

Figure 59.6 Sagittal T1-weighted magnetic resonance imaging scans of the hypothalamic-pituitary region in a patient with PP (a) and a patient with CDI (b). (a) A normal anterior pituitary (arrowhead) and pituitary stalk (thin *white arrow)* and hyperintensity of the posterior pituitary (thick *white arrow).* (b) Sagittal T1-weighted scan obtained in a patient with CDI due to lymphoma shows a massively thickened pituitary stalk (thin *white arrow)* and an absent hyperintense signal in the posterior pituitary gland (arrowhead). *(Reproduced with permission from Journal of Clinical Endocrinology and Metabolism 2012;97:3426–37, Wiebke Fenske and Bruno Allolio. Clinical Review: Current State and Future Perspectives in the Diagnosis of Diabetes Insipidus.)*

diabetes (possibly due to ADH store depletion secondary to over-secretion)[28] and in up to 30% of elderly subjects without any clinical symptoms of DI.[83] Additionally, the signal intensity may change bi-directionally over time, even in young subjects.[84] Given these findings, MRI-derived diagnostic information should probably be considered indicative rather than conclusive.

OTHER TESTS

Other tests have been explored to investigate polyuric syndromes in patients believed to have DI. Non-osmotic stimuli of ADH release such as nicotine, nausea and hypotension are not considered sufficiently reliable or consistent to be of practical use. More promisingly, it appears that the biochemically stable C-terminal glycoprotein cleaved from the ADH pro-hormone at the time of pro-hormone activation is relatively easy to measure and correlates well with plasma ADH concentrations. This 'plasma copeptin' may offer a future alternative to ADH for measurement during standard water deprivation and hypertonic saline tests.[85]

Thyroid emergencies

Jonathan M Handy and Alexander M Man Ying Li

Thyroid emergencies are a rare cause for admission to critical care. However, mortality is high unless specific treatment is provided in an expeditious manner. Abnormal thyroid function tests are commonly encountered during critical illness; numerous factors must be considered before interpreting these findings as indicating thyroid disease.

BASIC PHYSIOLOGY

Thyroid hormones affect the function of virtually every organ system and must be constantly available for these functions to continue. The two biologically active hormones are tetraiodothyronine (thyroxine or T_4) and tri-iodothyronine (T_3). These are synthesised by incorporating iodine into tyrosine residues, a process which occurs in thyroglobulin contained within the lumena of the thyroid gland (**Fig. 60.1**). Stimulation of hormone release by thyroid-stimulating hormone (TSH) results in endocytosis of thyroglobulin from the lumen into the follicular cells, followed by hydrolysis to form T_4 and T_3, which are released into the circulation.[1]

Both T_4 and T_3 contain two iodine atoms on their inner (tyrosine) ring. They differ in that T_4 contains two further iodine atoms on its outer (phenol) ring whereas T_3 contains only one, resulting in a comparatively longer plasma half-life for T_4 of 5–7 days compared with that of 10 hours for T_3. T_4 is produced solely by the thyroid gland whereas the majority of T_3 is synthesised peripherally by the removal of one iodine atom (deiodination) from the outer ring of T_4. If deiodination of an inner ring iodine atom occurs, the metabolically inert reverse-T_3 (rT_3) is formed. This is produced in preference to T_3 during starvation and many non-thyroidal illnesses, and the ratio of inactive (rT_3) to active T_3 synthesis appears to play an important role in the control of metabolism.[2] Numerous factors can affect the peripheral deiodination process (**Box 60.1**). Both T_4 and T_3 are highly protein bound in the serum, predominantly to thyroid-binding globulin (TBG), but to a lesser extent to albumin and pre-albumin. Changes in concentration of these serum-binding proteins have a large effect on total T_4 and T_3 serum concentrations. Such protein changes do not, however, effect the concentration of free hormone or their rates of metabolism. The serum-binding proteins act as both a store and a buffer to allow an immediate supply of the metabolically active free-T_4 (fT_4) and free-T_3 (fT_3). In addition, protein binding reduces the glomerular filtration and renal excretion of the hormones.

On reaching the target organs, fT_4 and fT_3 enter the cells predominantly by diffusion. Here, microsomal enzymes deiodinate the fT_4 to form fT_3. This varies in differing tissues, the majority occurring in the liver, kidney and muscle. The fT_3 subsequently diffuses into the nucleus where it binds nuclear receptors and exerts its affect through stimulation of messenger RNA (mRNA) with subsequent synthesis of polypeptides including hormones and enzymes. The role of thyroid hormones in development and homeostasis is widespread and profound; the most obvious effects are to stimulate basal metabolic rate and sensitivity of the cardiovascular and nervous systems to catecholamines.

The regulation of thyroid function is predominantly determined by three main mechanisms, the latter two providing physiological control. First, availability of iodine is crucial for the synthesis of the thyroid hormones. Dietary iodide is absorbed and rapidly distributed in the extracellular fluid, which also contains iodide released from the thyroid gland and from peripheral deiodination processes. This becomes trapped within thyroid follicular cells, from which it is actively transported into the lumen to be oxidised into iodine and subsequently combined with tyrosine.[3] Other ions such as perchlorate and pertechnetate share this follicular cell active transport mechanism and thus act as competitive inhibitors for the process.

Secondly, thyroid hormone release is controlled by a close feedback loop with the anterior pituitary. Diminished levels of circulating hormones trigger secretion of TSH, which acts on the follicular cells of the thyroid gland causing them to release thyroglobulin-rich colloid from the lumena. This thyroglobulin is hydrolysed to form T_4 and T_3 for systemic release. Increased levels of T_4 and T_3 cause diminished TSH secretion, resulting in the follicular cells becoming flat and allowing increased capacity for colloid storage. As a result, less thyroglobulin is mobilised and hydrolysed with less T_4 and T_3 release. The degree to which TSH is secreted in response to changes in circulating thyroid hormones is

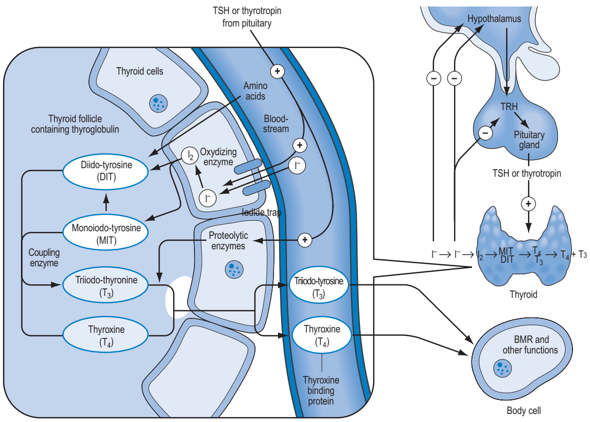

Figure 60.1 Synthesis of tetraiodothyronine (T_4) and tri-iodothyronine (T_3). Stimulation of hormone release by thyroid-stimulating hormone (TSH) produced in the pituitary gland results in endocytosis of thyroglobulin from the lumen into the follicular cells, followed by hydrolysis to form T_4 and T_3, which is released into the circulation.

Box 60.1 States associated with decreased deiodination of T_4 to T_3

- Systemic illness
- Fasting
- Malnutrition
- Postoperative state
- Trauma
- Drugs: propylthiouracil, glucocorticoids, propanolol, amiodarone
- Radiographic contrast agents (ipodate, ipanoate)

dependent on the hypothalamic hormone thyrotropin-releasing hormone (TRH), which is itself modulated by feedback from the thyroid hormones (see Fig. 60.1). TRH secretion is inhibited by dopamine, glucocorticoids and somatostatin.

Lastly, further regulation occurs during the enzyme-dependent peripheral conversion of fT_4 to fT_3. It is this latter stage that provides the rapid and fine control of local fT_3 availability. All of these mechanisms may be altered by drugs and in pathological states.

THYROID CRISIS (THYROID STORM)

Thyrotoxic storm is arguably the most serious complication of hyperthyroidism, with reported mortality ranging from 10 to 75% in hospitalised patients.[4,5] Crisis most commonly occurs as a result of unrecognised or poorly controlled Grave's disease; however, other underlying diseases may be the cause.[6,7] Females outnumber males. Laboratory findings are inconsistent owing to acute disruption of the normal steady state of the circulating hormones and there is no definitive value that separates thyrotoxicosis from thyroid storm. The latter is a clinical diagnosis, and a scoring system has been proposed to guide the likelihood of the diagnosis (**Table 60.1**).[8] Precipitating factors are not always present, though many have been identified (**Box 60.2**).

CLINICAL PRESENTATION (Box 60.3)

The classic signs of thyroid crisis include fever, tachycardia, tremor, diarrhoea, nausea and vomiting.[9] However, presentation is extremely variable and may range from apathetic hyperthyroidism (apathy, depression, hyporeflexia and myopathy)[10] to multiple organ

Table 60.1 Severity assessment in thyroid crisis*

TEMP (°C)	PULSE	CARDIAC FAILURE	CNS EFFECTS	GI SYMPTOMS	SCORE
Normal	<99	Absent	Normal	Normal	0
37.2–37.7	99–109	Pedal oedema	—	—	5
37.8–38.2	110–119	Bibasal crepitations, atrial fibrillation	Agitation	Diarrhoea, nausea, vomiting, abdominal pain	10
38.3–38.8	120–129	Pulmonary oedema	—	—	15
38.9–39.3	130–139	—	Delirium	Unexplained jaundice	20
39.4–39.9	>140	—	—	—	25
>40	—	—	Seizure, coma	—	30

*Adapted from Tietgens ST, Leinung MC. Thyroid storm. Medical Clinics of North America, 1995;79:169–184.
Calculations:
1. Add the scores for each of the five clinically observed parameters.
2. Add a further *10 points* if *atrial fibrillation* is present.
3. Add a further *10 points* if an identifiable *precipitating factor* is present.
4. Total score of *45* or greater is highly suggestive of thyroid storm. Total score of *25–44* supports impending crisis. Total score of less than *25* makes thyroid storm unlikely.
CNS=central nervous system; GI=gastrointestinal.

Box 60.2 Factors associated with precipitating thyroid storm

- Infection; sepsis
- Withdrawal of antithyroid treatment
- Surgery; trauma
- Parturition
- Diabetic ketoacidosis
- Radioactive iodine therapy
- Iodinated contrast dyes
- Hypoglycaemia
- Excessive palpation of the thyroid gland
- Emotional stress
- Burn injury
- Pulmonary thromboembolism
- Cerebrovascular accident; seizure disorder (including eclampsia)
- Thyroid hormone overdose

dysfunction.[11,12] Differential diagnosis includes sepsis and other causes of hyperpyrexia such as adrenergic and anticholinergic syndromes.

FEVER

This is the most characteristic feature. Temperature may rise above 41°C. There have been suggestions that pyrexia is present in all cases of thyroid storm,[13] though normothermia has also been reported.[11] Pyrexia is rare in uncomplicated thyrotoxicosis and should always raise suspicion of thyroid storm. It is not clear whether this febrile response is due to alteration of central thermoregulation or elevation of basal metabolic thermogenesis beyond the body's ability to lose heat.

CARDIOVASCULAR FEATURES

Fluid requirements may be substantial in some patients, whereas diuresis may be required in those with severe heart failure. Cardiac decompensation can occur in young patients with no known antecedent cardiac disease. Systolic hypertension with widened pulse pressure is common initially; however, hypotension supervenes later. Shock with vascular collapse is a pre-terminal sign.[14]

NEUROMUSCULAR FEATURES

Tremor is a common early sign, but as 'storm' progresses central nervous dysfunction evolves with progression from agitation and anxiety to encephalopathy or even coma.[15] Thyroid storm has been reported in association with status epilepticus and cerebrovascular accident.[16] Weakness may be a feature, particularly with apathetic thyrotoxicosis.[11] Thyrotoxic myopathy and rhabdomyolysis may be present,[11,17] the latter being differentiated from the former by its association with markedly elevated creatine phosphokinase levels. A number of other syndromes of neuromuscular weakness have been described including hypokalaemic periodic paralysis[18,19] and myasthenia gravis.[20]

Box 60.3 Clinical features of hyperthyroidism/thyroid crisis

- Fever
- Cardiovascular:
  - Tachycardia, atrial fibrillation, ventricular arrhythmias
  - Heart failure
  - Hypertension (early), hypotension (late)
- Neuromuscular:
  - Tremor
  - Encephalopathy, coma
  - Weakness
- Gastrointestinal:
  - Diarrhoea, nausea and vomiting
- Respiratory:
  - Dyspnoea
  - Increased oxygen consumption and carbon dioxide production
- Goitre (possible airway compromise)
- Laboratory abnormalities

GASTROINTESTINAL FEATURES

Diarrhoea, nausea and vomiting are common, though the patient may present with symptoms of an acute abdomen.[21] Severe abdominal tenderness should raise the possibility of an abdominal emergency. Liver function tests may be abnormal due to congestion or necrosis and tenderness over the hepatic area may be present. Hepatosplenomegaly may be present. The presence of jaundice is a poor prognostic sign.[14]

RESPIRATORY CONSIDERATIONS

Dyspnoea at rest or on exertion may be present for a number of reasons. Oxygen consumption and carbon dioxide production are increased with subsequent increase in the respiratory burden. This may be exacerbated by pulmonary oedema, respiratory muscle weakness and tracheal obstruction from enlarged goitre (rare).

LABORATORY FINDINGS

Numerous abnormalities may be found:

- fT_4 and fT_3 are usually increased, though this does not correlate with clinical severity; TSH is undetectable
- hyperglycemia in non-diabetics
- leucocytosis with a left shift, even in the absence of infection (leucopenia may be present in patients with Graves' disease)
- abnormal liver function tests and hyperbilirubinaemia
- hypercalcemia due to haemoconcentration and the effect of thyroid hormones on bone resorption
- hypokalaemia and hypomagnesaemia (particularly in apathetic thyrotoxicosis)

- serum cortisol should be elevated – if low values are found, adrenal insufficiency should be considered and treated; adrenal reserve in thyrotoxic patients is often exceeded in the absence of absolute adrenal insufficiency.

MANAGEMENT

Treatment is aimed at:

- control and relief of adrenergic symptoms
- correction of thyroid hormone abnormalities
- the precipitating cause
- investigation and treatment of the underlying thyroid disease
- supportive measures.

BETA-ADRENERGIC BLOCKADE

This is the mainstay of controlling adrenergic symptoms.[22] Intravenous propranolol titrated in 0.5–1mg increments while monitoring cardiovascular response diminishes the systemic hypersensitivity to catecholamines. In addition it inhibits peripheral conversion of T_4 to T_3.[23] Concurrent administration of enteral propranolol is the norm, with doses as high as 60–120 mg 4–6-hourly often being necessary owing to enhanced elimination during thyroid crisis.[24] An alternative regimen uses intravenous esmolol with a loading dose of 250–500 μg/kg followed by infusion at 50–100 μg/kg/min. This allows rapid titration of beta blockade while minimising adverse reactions.[25] Patients with contraindications to beta blockade or who exhibit resistance to this treatment may be successfully treated with reserpine or guanethidine, though their onset of action is slow and side-effects may be significant.

DIGOXIN

Control of heart rate and rhythm may result in significant improvement in cardiac performance. Electrolyte imbalance, particularly hypokalaemia and hypomagnesaemia, should be corrected prior to drug therapy. Relative resistance to digoxin may occur due to increased renal clearance[26] and increased Na/K ATPase units in cardiac muscle.[27] Arterial thromboembolic phenomena are common (10–40%) in thyrotoxicosis-related atrial fibrillation. This may be due to a procoagulant state or an increased incidence of mitral valve prolapse. Anticoagulation is controversial given the increased sensitivity to warfarin and potential for bleeding; however, it should be considered in the management of these patients.

AMIODARONE

Amiodarone has theoretical benefits in thyrotoxicosis as it inhibits peripheral conversion of T_4 to T_3 and reduces the concentration of T_3-induced adrenoceptors in cardiac myocytes.[28] It does, however, cause profound (and sometimes physiologically irrelevant) changes to thyroid function tests and should not therefore be used as the first-line agent.

THIONAMIDES

These drugs block de novo synthesis of thyroid hormones within 1–2 hours of administration, but have no effect on the release of preformed glandular stores of thyroid hormones. Transient leucopenia is common (20%) and agranulocytosis can rarely occur with carbimazole use.

Propylthiouracil

This is usually considered the drug of choice in thyroid storm owing to its ability to partially block peripheral conversion of T_4 to T_3. Its main mechanism of action is to block the iodination of tyrosine. Only enteral preparations are available and absorption may be unpredictable during thyroid crisis. Rectal administration has been reported. The loading dose is 100 mg followed by 100 mg every 2 hours.

Methimazole

Methimazole lacks peripheral effects, but has a long duration of action making administration easier and more reliable. It may be used in combination with drugs that block peripheral T_4-to-T_3 conversion (such as iopanoate or ipodate). Only enteral preparations are available, though rectal administration has been reported. Loading dose is 100 mg followed by 20 mg every 8 hours.

Carbimazole

This is metabolised to methimazole and is rarely associated with agranulocytosis. Only enteral preparations are available.

IODINE

The release of preformed glandular thyroid hormones is inhibited by administering either inorganic iodine or lithium. Enterally administered iodides include Lugol's solution and sodium or potassium iodide. Intravenous infusion of sterile sodium iodide may be used at a dose of 1 g 12-hourly; however, this is not always available commercially. If not, it may be prepared by the hospital pharmacy. Iodine therapy should not commence without prior thionamide administration. Used alone, it will enrich hormone stores within the thyroid gland and exacerbate thyrotoxicosis.

Iodine-containing contrast media (e.g. ipodate and iopanoate) may be used instead of the simple iodides, the former blocking T_4-to-T_3 conversion and inhibiting the cardiac effects of thyroxine. Ipodate is administered orally as a loading dose of 3 g followed by 1 g daily. As with the iodides, treatment should always be preceded by thionamide administration.

LITHIUM

Lithium carbonate has a similar, though weaker, action to iodine and can be used in patients with iodine allergy. An initial dose regimen of 300 mg 6-hourly has been used with subsequent dosage adjusted to maintain serum drug levels at about 1 mmol/L.[29] Renal and neurological toxicity tend to limit its use.

STEROIDS

Glucocorticoids reduce T_4-to-T_3 conversion and may modulate any autoimmune process underlying the thyroid crisis (e.g. Graves' disease). In addition, relative glucocorticoid deficiency may be a feature of the crisis. An ACTH stimulation test is desirable prior to administration of hydrocortisone (100 mg 6- to 8-hourly); alternatively dexamethasone (4 mg 6-hourly) can be administered until the test has been performed. Combination therapy with iodides can produce rapid results. Glucocorticoids are the most effective treatment for type-2 amiodarone-induced thyrotoxicosis.[30]

OTHER THERAPIES

Plasmapheresis, charcoal haemoperfusion and dantrolene have all been used as novel therapies in thyroid storm; however, their use is not established or proven.

SUPPORTIVE THERAPY

Fluid management

Fluid management may be extremely difficult in patients suffering from thyroid storm, particularly the elderly. Fluid losses may be profound due to diarrhoea, vomiting, pyrexia and reduced intake. However, congestive cardiac failure may also develop as a result of the high cardiac demand. Echocardiography and cardiac output monitoring may be invaluable in guiding therapy for such patients.

Nutrition

Thyrotoxic patients have high energy expenditure and may present with a significant energy, vitamin and nitrogen deficit. Nutritional requirements should take account of any deficit and the ongoing hypercatabolic state. Thiamine is usually supplemented.

Drug therapy

Consideration should be given to the enhanced metabolism and elimination of drugs that occurs in thyrotoxic patients. Salicylates and furosemide should be avoided as both displace thyroid hormones from their binding proteins and can rapidly exacerbate systemic symptoms.

Precipitating factors

Both the precipitating factors and the disease process underlying the thyroid crisis should be sought and treated aggressively. Infection is the leading precipitant of crisis; thus early microbiological cultures and antibiotic therapy should be considered.

MYXOEDEMA COMA

Myxoedema coma is the extreme manifestation of hypothyroidism, which, although rare, carries a mortality ranging from 30 to 60%. The term is a misnomer in that the majority of patients present with neither the non-pitting oedema known as myxoedema nor coma.[31]

Box 60.4 Factors precipitating myxoedema coma

- Infection
- Cold environmental temperatures/hypothermia
- Burns
- Stroke
- Surgery
- Trauma
- Chronic heart failure
- Carbon dioxide retention
- Gastrointestinal haemorrhage
- Hypoglycaemia
- Carbon dioxide retention
- Gastrointestinal haemorrhage
- Hypoglycaemia
- Medications:
  - Amiodarone
  - Anaesthetic agents
  - Analgesics/narcotics
  - Beta blockers
  - Diuretics
  - Lithium
  - Phenytoin
  - Rifampicin
  - Sedatives/tranquilisers

The condition should be considered in any patient presenting with a reduced level of consciousness and hypothermia. The crisis occurs most commonly in elderly women with long-standing undiagnosed or undertreated hypothyroidism in whom an additional significant stress is experienced. Numerous precipitating factors have been identified (**Box 60.4**).

CLINICAL PRESENTATION (Box 60.5)

Myxoedema coma can be defined when decreased mental status, hypothermia and clinical features of hypothyroidism are present (Box 60.5). When these features are present, diagnosis is straightforward; however, asymptomatic or atypical presentation (e.g. decreased mobility) may occur.[32] The presence of hypotension and bradycardia at presentation, a need for mechanical ventilation, hypothermia unresponsive to treatment, sepsis, intake of sedative drugs, lower GCS, high APACHE II score, and high SOFA score have been associated with an increased predicted mortality.[33]

NEUROMUSCULAR

Alteration of conscious or mental state is present in all patients. This can range from personality changes to coma, with about 25% of patients experiencing seizures prior to the onset of coma. Electroencephalogram usually reveals non-specific changes. Weakness is common and skeletal muscle dysfunction may develop secondary to increased membrane permeability. The latter can lead to a rise in creatine phosphokinase. Hyponatraemia is present in up to 50% of patients and

Box 60.5 Clinical features of myxoedema coma

- Neuromuscular
  - Abnormal conscious level
  - Psychiatric alterations
  - Weakness
  - Slow relaxing reflexes
  - Fatigue
- Hypothermia
- Cardiovascular
  - Diastolic hypertension
  - Bradycardia
  - Low cardiac output
  - Pericardial effusions
  - ECG alterations
- Respiratory
  - Diminished central response to hypoxia and hypercapnia
  - Respiratory alkalosis
  - Respiratory muscle weakness
  - Increased sensitivity to sedative drugs
  - Pleural effusions
  - Sleep apnoea
- Airway
  - Deep voice, goitre, vocal cord oedema, macroglossia

  - Ascites (rare)
- Bladder distension, urinary retention
- Cold intolerance
- Coarse hair
- Dry, pale, cool skin
- Laboratory abnormalities

may contribute to alterations in conscious level (see below). Lumbar puncture often reveals elevated protein levels and a high opening pressure.

HYPOTHERMIA

Hypothermia represents the decrease in thermogenesis that accompanies reduced metabolism and is exacerbated by low ambient temperatures. Mortality is proportional to the degree of hypothermia. A low-reading thermometer should be used during assessment.

CARDIOVASCULAR FEATURES

Diastolic hypertension is due to increased systemic vascular resistance and blood volume reduction.[34] However, myxoedema is associated with bradycardia and impaired myocardial contractility, with reduced cardiac output and hypotension a common feature. Although pericardial effusions may occur, tamponade is uncommon. Creatine phosphokinase may be elevated, though this more commonly originates from skeletal than from cardiac muscle. Acute coronary syndrome must nevertheless be excluded as a precipitant of the crisis. ECG changes include bradycardia, decreased voltage, non-specific ST and T changes, varying types of block and prolonged QT interval. All of the cardiovascular abnormalities are reversible with thyroid hormone treatment.[35]

RESPIRATORY FEATURES

Hypothyroidism causes numerous respiratory alterations (see Box 60.5). There is a propensity to respiratory alkalosis, particularly during artificial ventilation. This is due to low metabolic rate which may be compounded by iatrogenic hyperventilation.[36] Diaphragmatic weakness may occur owing to abnormalities of the phrenic nerve; as a result, exercise tolerance may be significantly reduced. These abnormalities improve with thyroid hormone replacement, though full recovery can take several months.

LABORATORY FINDINGS

Thyroid function tests will reveal low T_4 and T_3; TSH is raised in primary and low in secondary and tertiary hypothyroidism.

Hyponatraemia is common and usually develops owing to free water retention resulting from excess vasopressin secretion or impaired renal function.[37] It may be severe and can contribute to diminished mental function. Although total body water is increased, intravascular volume is usually decreased.

Hypoglycaemia may result from hypothyroidism alone, or as a result of concurrent adrenal insufficiency (Schmidt's syndrome). The mechanism is probably reduced gluconeogenesis, but infection and starvation may contribute.

Azotaemia and hypophosphataemia are common; renal function may be severely abnormal owing to low cardiac output and vasoconstriction. Mild leucopenia and normocytic anaemia are frequently present, though macrocytic and pernicious anaemia due to autoimmune dysfunction may occur.

Arterial blood gases often reveal respiratory acidosis, hypoxia and hypercapnia.

MANAGEMENT

The mainstay of therapy consists of thyroid hormone replacement, steroid replacement and supportive measures. Once clinical diagnosis has been made or is suspected, blood should be collected for thyroid function and plasma cortisol tests. This should be followed by thyroid hormone treatment, which should not be delayed to await laboratory results. Consideration should be given to identifying and treating precipitating factors and complications of the crisis.

THYROID HORMONE THERAPY

All patients with suspected myxedema coma should receive presumptive treatment with thyroid hormone.

The optimum speed, type, route and dose of thyroid hormone replacement in myxoedema coma are unknown owing to the rarity of the condition and paucity of trials. The severity of clinical presentation does not correlate with the doses of replacement hormone that are required. Rapid replacement can result in life-threatening myocardial ischaemia or arrhythmias; delayed therapy exposes patients to prolonged risk of complications from the crisis. Both scenarios are associated with increased mortality.

Some experts favour administration of T_3 as it is biologically more active; has more rapid onset of action, and bypasses the impaired deiodination of T_4 to T_3 that occurs in hypothyroidism and non-thyroidal illness. High serum T_3 concentration has, however, been associated with increased mortality[38] and T_3 is expensive and may be difficult to obtain. T_3 may be administered orally or intravenously and has been combined with T_4 therapy.[39,40] In one study of 23 successive patients suffering from myxoedema coma, those who received oral L-thyroxine had no difference in outcome from those receiving i.v. thyroxine.[33]

Most authorities recommend use of T_4 alone[38,40,41] as the delayed conversion to T_3 allows more gradual replacement of the deficient hormone. Bioavailability of orally administered T_4 is unpredictable given the high incidence of gastrointestinal dysfunction; therefore intravenous administration is more frequently used. A loading dose of intravenous levothyroxine 100–500 μg is recommended[40] as this saturates the binding proteins. This should be followed by 50–100 μg daily until conversion to the bioequivalent oral formulation is possible. The doses must be adjusted to allow for patient age, weight and their cardiovascular risk factors; the lower doses should be administered to patients who are elderly, frail or have co-morbidities (particularly cardiovascular disease).

CORTICOSTEROIDS

Corticosteroids are an important part of treatment as relative or absolute hypoadrenalism may occur concurrently with hypothyroid disease. A random serum cortisol level should be collected prior to commencing hydrocortisone therapy at 100 mg 8-hourly. If ACTH stimulation test is warranted, dexamethasone 4 mg 6-hourly should be commenced with conversion to hydrocortisone or cessation of treatment once the results are known. If random serum cortisol levels return at normal levels, steroid treatment can be discontinued.

SUPPORTIVE THERAPY

Hypothermia should be treated by passive rewarming where possible, but active measures may be required. Appropriate cardiovascular, temperature gradient, electrolyte and acid–base monitoring should be provided during the rewarming phase in order to prevent haemodynamic and metabolic compromise.

Numerous alterations in respiratory physiology occur, including hypoventilation and altered response to arterial oxygen and carbon dioxide tensions. In addition, anatomical changes to the airway, delayed gastric emptying and increased sensitivity to sedative drugs may be present. These changes should be considered when mechanical ventilation is required; particularly during intubation and the weaning process.[36]

Patients usually present with intravascular fluid depletion despite peripheral oedema. Cardiac output monitoring may help guide fluid resuscitation and therapy. Echocardiography is useful in identifying cardiac dysfunction, pericardial effusions and assisting in assessment of intravascular volume status. Cardiac monitoring should be used to alert to the presence of arrhythmias. Inotropes and vasopressors should be avoided where possible owing to their potential to precipitate cardiac arrhythmias. Where inotropes are required, increased dosage may be necessary as reduction in β-adrenoceptors is common; α-adrenoceptor function is usually preserved.

Hyponatraemia is reversible with thyroid hormone treatment, but severe abnormalities contributing to neurological dysfunction may require more expeditious correction. Free water intake should be restricted and hypertonic saline solutions may be required. Hypotonic fluid therapy should be avoided. If glucose therapy is required, hypertonic solutions (20–50%) should be infused via a central venous catheter.

Precipitating factors must be considered. As with all critically ill patients, microbial cultures should be collected and antibiotic therapy commenced unless cultures are negative. Prophylaxis against venous thromboembolism and peptic ulceration should be considered. Enteral feeding should be attempted, but may be unsuccessful if gastrointestinal dysfunction and stasis is present.

NON-THYROIDAL ILLNESS

Non-thyroidal illness describes the phenomenon of starved or systemically unwell patients with abnormal serum thyroid function tests but with no apparent thyroidal illness. Low T_3, T_4 and TSH are commonly found, the degree of abnormality correlating with the severity of illness. Variants of these hormone levels are well described. Low serum T_3 is a frequent finding and occurs due to down-regulation of the monodeiodinase enzyme that converts T_4 to T_3, while rT_3 may increase owing to increased activity of the T_4-to-T_3 monodeiodinase.[42]

Serum T_4 is also commonly low in the critically ill. This is due to a decrease in the concentration of thyroid hormone-binding proteins and the presence of inhibitors that reduce T_4 binding to these proteins. There is also suggestion that T_4 entry into cells may be impaired.[43] Free T_4 levels should be normal in less severe illness; however, in severe illness the level may

be low owing to inadequate correction during the fT_4 assay.[44]

Low serum TSH levels were previously thought to be associated with the euthyroid state; however, more recent work suggests that acquired transient central hypothyroidism is present in these patients.[45] Cytokines such as tumour necrosis factor-α are known to inhibit TSH secretion. Such phenomena are probably evolutionary adaptations to conserve protein and energy during severe illness. Elevated TSH may also occur in non-thyroidal illness, but few of these patients prove to have hypothyroidism following recovery from their acute illness.

Changes in thyroid function test (TFT) are well described during starvation, sepsis, bone marrow transplantation, surgery, myocardial infarction, coronary artery bypass surgery, and probably any critical illness. However, replacement of thyroid hormone in these patients is of no benefit and may be harmful;[46] hence thyroid function should not be assessed in critically ill patients unless there is a strong clinical indication to do so. A number of specific non-thyroidal illnesses are associated with abnormal TFTs. These include: some psychiatric illnesses, hepatic disease, nephritic syndrome, acromegaly, acute intermittent porphyria and Cushing's syndrome. Where assays are performed, TSH should not be interpreted in isolation as low values will not discriminate between true thyroid versus non-thyroidal disease. If low T_4 is also present, non-thyroidal illness is likely. If T_4 is elevated then hyperthyroidism is the likely diagnosis, though elevated T_4 has been documented in non-thyroidal illness.

Given the alterations in these hormones and difficulties with their assay during critical illness, thyroid hormone replacement should not be undertaken on the strength of TFT results alone. Additional laboratory and clinical indications must also be present (**Table 60.2**).

Table 60.2 Changes in thyroid hormone concentrations

	fT_4	T_3	TSH
Euthyroid	N	N	N
Hyperthyroid	↑	↑	↓
Hypothyroid	↓	↓ N	↑
Non-thyroidal illness	↑ N ↓	↓	N ↓

fT_4=free tetraiodothyronine; T_3=tri-iodothyronine; TSH=thyroid-stimulating hormone; N=normal; ↑=increased; ↓=decreased.

Adrenocortical insufficiency in critical illness

Balasubramanian Venkatesh and Jeremy Cohen

The adrenal glands form an essential part of the organism's response to stress. Hence, in intensive care, an adequate adrenal response is considered to be of prime importance. Although primary adrenal insufficiency is a well-recognised but rare condition in intensive care, secondary, or relative, adrenal insufficiency is thought to be more prevalent. Adrenocortical insufficiency may present as an insidious, occult disorder, unmasked by conditions of stress, or as a catastrophic syndrome that may result in death.

PHYSIOLOGY

The adrenal glands are functionally divided into medulla and cortex; the latter is responsible for the secretion of three major classes of hormones: glucocorticoids, mineralocorticoids and sex hormones. The major pathogenic effects of disease result from cortisol and aldosterone deficiency.

Cortisol, the major glucocorticoid (GC) synthesised by the adrenal cortex, plays a pivotal role in normal metabolism. It is necessary for the synthesis of adrenergic receptors, normal immune function, wound healing and vascular tone. These actions are mediated by the glucocorticoid receptor, a member of the nuclear hormone receptor superfamily. The activated receptor migrates to the nucleus and binds to specific recognition sequences within target genes, but also interacts with numerous transcription factors and cytosolic proteins. Numerous isoforms of the glucocorticoids receptor have now been described; the alpha subtype, a 777-amino-acid polypeptide chain, was initially felt to be the primary mediator of glucocorticoid action. In contrast the beta isoform, a 742-amino-acid chain, was felt to have no physiological activity. More recently it appears that the beta subtype has a negative effect on alpha-mediated gene transactivation, the physiological relevance of which remains controversial. Furthermore, additional isoforms have now been described, suggesting that glucocorticoid receptor diversity may be an important factor in understanding the complex effects of corticosteroid action.[1]

Under normal circumstances, cortisol is secreted in pulses, and in a diurnal pattern.[2] The normal basal output of cortisol is estimated to be 15–30 mg/day, producing a peak plasma cortisol concentration of 110–520 nmol/L (4–19 μg/dL) at 8–9 a.m., and a minimal cortisol level of <140 nmol/L (<5 μg/dL) after midnight. The daily output of aldosterone is estimated to be 100–150 μg/day.

Secretion is under the control of the hypothalamic–pituitary axis. There are a variety of stimuli to secretion, including stress, tissue damage, cytokine release, hypoxia, hypotension and hypoglycaemia. These factors act upon the hypothalamus to favour the release of corticotrophin-releasing hormone (CRH) and vasopressin. CRH is synthesised in the hypothalamus and carried to the anterior pituitary in portal blood, where it stimulates the secretion of adrenocorticotrophic hormone (ACTH), which in turn stimulates the release of cortisol, mineralocorticoids (principally aldosterone) and androgens from the adrenal cortex. CRH is the major (but not the only) regulator of ACTH release and is secreted in response to a normal hypothalamic circadian regulation and various forms of 'stress'. Vasopressin, oxytocin, angiotensin II and beta-adrenergic agents also stimulate ACTH release, whereas somatostatin, beta endorphin and enkephalin reduce it. Cortisol has a negative feedback on the hypothalamus and pituitary, inhibiting hypothalamic CRH release induced by stress and pituitary ACTH release induced by CRH. During periods of stress, trauma or infection, there is an increase in CRH and ACTH secretion and a reduction in the negative-feedback effect, resulting in increased cortisol levels in amounts roughly proportional to the severity of the illness.[3–5]

Cortisol is transported in the blood to the tissues in three fractions: approximately 80% is closely bound to corticosteroid-binding globulin (CBG), 10–15% is loosely bound to albumin, and 5–8% is a free fraction. At normal levels of total plasma cortisol (e.g. 375 nmol/L or 13.5 μg/dL) less than 5% exists as free cortisol in the plasma; however, it is this free fraction that is biologically active. Circulating CBG concentrations are approximately 700 nmol/L. In normal subjects CBG can bind approximately 700 nmol/L (i.e. 25 μg/dL).[6] At levels greater than this, the increase in plasma cortisol is largely in the unbound fraction. The affinity of CBG for synthetic corticosteroids, with the exception of prednisolone, is negligible. CBG is a substrate for elastase, a polymorphonuclear enzyme that cleaves CBG, markedly decreasing its affinity for cortisol.[7] This

enzymatic cleavage results in the liberation of free cortisol at sites of inflammation. CBG levels have been documented to fall during critical illness,[8–10] and these changes are postulated to increase the amount of circulating free cortisol.

Cortisol is lipophilic and diffuses into the cell freely. However, once inside the cell the concentrations of cortisol are profoundly affected by the activity of the 11β-hydroxysteroid dehydrogenase 1 and 2 (11β-HSD1 and 2) enzyme system.[11–14] 11β-HSD1 acts in vivo primarily as a reductase, generating active cortisol from inactive cortisone. By contrast, 11β-HSD2 has dehydrogenase action, inactivating cortisol by conversion to cortisone. 11β-HSD2 is found primarily in mineralocorticoid target tissues such as kidney, sweat glands and colonic mucosa, where it prevents illicit activation of the mineralocorticoid receptor by cortisol. 11β-HSD1 has a wide distribution including liver, adipose and vascular tissues and, although its primary action is reductase, there is some evidence its directionality may be tissue specific.[15] The system is able to regulate intracellular GC concentration irrespective of circulation concentration, thus rendering circulating levels highly problematic as indicators of tissue GC activity. Altered HSD status has been reported in critical illness.[16,17]

Cortisol has a half-life of 70–120 minutes. It is eliminated primarily by hepatic metabolism and glomerular filtration. The excretion of free cortisol through the kidney represents 1% of the total secretion rate. Currently, available routine assays measure only total cortisol levels: bound and free.

The metabolic effects of cortisol are complex and varied. In the liver, cortisol stimulates glycogen deposition by increasing glycogen synthase and inhibiting the glycogen-mobilising enzyme glycogen phosphorylase.[18] Hepatic gluconeogenesis is stimulated, leading to increased blood glucose levels. Concurrently, glucose uptake by peripheral tissues is inhibited.[19] Free fatty acid release into the circulation is increased, and triglyceride levels rise.

In the circulatory system, cortisol increases blood pressure both by direct actions upon smooth muscle and via renal mechanisms. The actions of pressor agents such as catecholamines are potentiated, whereas nitric-oxide-mediated vasodilation is reduced.[20,21] Renal effects include both an increase in glomerular filtration rate and sodium transport in the proximal tubule and sodium retention and potassium loss in the distal tubule.[22]

The primary effects of cortisol upon the immune system are anti-inflammatory and immunosuppressive. Lymphocyte cell counts decrease, whereas neutrophil counts rise.[22] Accumulation of immunologically active cells at inflammatory sites is decreased. The production of cytokines is inhibited, an effect that is mediated via nuclear factor κB (NF-κB). This occurs by induction of NF-κB inhibitor or by direct binding of cortisol to NF-κB, thus preventing its translocation to the nucleus.

Although the well-defined effects of cortisol upon the immune system are primarily inhibitory, it is also suggested that normal host defence function requires some cortisol secretion. Cortisol has been described to have a positive effect upon immunoglobulin synthesis, potentiation of the acute phase response, wound healing, and opsonisation.[23]

CLASSIFICATION

Adrenal insufficiency (AI) may be considered to be primary, secondary or relative. Primary AI, otherwise known as Addison's disease, results from hypofunction of the adrenal cortex. Secondary AI occurs when there is suppression or absence of ACTH secretion from the anterior pituitary. Relative AI describes a situation of inadequate cortisol response to stress in the setting of critical illness.

PRIMARY ADRENAL INSUFFICIENCY

Primary adrenal insufficiency or Addison's disease is a rare disorder. In the Western world its estimated prevalence is 120 per million.[24] In adulthood, the commonest cause is autoimmune, but in the intensive care setting consideration should be given to other causes of adrenal gland destruction (**Box 61.1**). These include infection, haemorrhage and infiltration. Tuberculosis is the commonest infective cause worldwide, but rarer infections such as histoplasmosis, coccidiomycosis and cytomegalovirus (CMV), especially in patients with HIV, have also been implicated. Haemorrhage into the glands is associated with septicaemias, particularly meningococcal (Waterhouse–Fredrickson syndrome). Asplenia and the antiphospholipid syndrome may also be associated with adrenal haemorrhage. Adrenal gland destruction

Box 61.1 Causes of primary adrenal insufficiency

Infections
Tuberculosis
Histoplasmosis
Coccidiomycosis
Cytomegalovirus
Autoimmune mediated
Haemorrhagic
Sepsis (especially meningococcal)
Antiphospholipid syndrome
Trauma
Surgery
Coagulation disorders
Infiltrative
Tumour
Amyloid
Sarcoidosis
Haemochromatosis
Drug related
Etomidate
Fluconazole
Ketoconazole
Metyrapone
Suramin
Rifampicin
Phenytoin
Congenital
Adrenal dysgenesis
Adrenoleucodystrophy
Impaired steroidogenesis
Cytokine mediated

may also be secondary to infiltration with tumour, or amyloid.

Drugs may impair adrenal function either by inhibiting cortisol synthesis (etomidate, ketoconazole) or by inducing hepatic cortisol metabolism (rifampicin, phenytoin). High levels of circulating cytokines are also reported to have a suppressive effect upon ACTH release.[25]

*PRESENTATION (**BOX 61.2**)*

The disease is often unrecognised in its early stages as the presenting features are ill defined. Symptoms include tiredness and fatigue, vomiting, weight loss, anorexia and postural hypotension. Hyperpigmentation is seen in non-exposed areas (such as palmar skin creases) and is due to the hypersecretion of melatonin, a breakdown product from the ACTH precursor proopiomelanocortin (POMC).

Presentation to an intensive care physician is likely to be in the form of adrenal crisis. This may be precipitated by concurrent illness or surgery, or by failure to take replacement medication. Adrenal crisis will present classically as refractory shock with a poor response to inotropic or pressor agents. Abdominal or flank pain is often present and may lead to an erroneous diagnosis of an acute surgical abdomen.

Treatment should consist of immediate supportive measures, fluid resuscitation and high-dose intravenous glucocorticoid therapy. *A standard dose would be 100 mg of hydrocortisone 6-hourly, or as an infusion.* At these doses, separate mineralocorticoid replacement is not required.[26]

Adrenal crisis should be suspected in cases of undifferentiated shock not responding to standard management. Suggestive features would include a history of symptomatology consistent with the diagnosis, hyperpigmentation on examination, and demonstration of hyponatraemia, hyperkalaemia and peripheral blood eosinophilia. A random plasma total cortisol taken during a crisis will be low (below 80 nmol/L) and in the acute phase ACTH stimulation testing is not required.

Box 61.2 Clinical features of Addison disease

Symptoms	Signs
Muscular weakness	Hyperpigmentation – skin creases, buccal mucosa
Fatigue	Postural hypotension
Abdominal pain	Associated vitiligo
Vomiting	Decreased axillary and pubic hair
Diarrhoea	Auricular calcification
Salt craving	Vasodilated shock (in crisis)
Weight loss	
Arthralgia and myalgia	
Mood change	
Headache	
Sweating	
Syncope	

SECONDARY ADRENAL INSUFFICIENCY

The commonest cause of ACTH deficiency is sudden cessation of exogenous glucocorticoid treatment. Patients who have been taking more than 30 mg/day of hydrocortisone or the equivalent for more than 3 weeks are at risk of adrenal suppression.[22] Other causes include pituitary surgery, pituitary infarction (Sheehan syndrome) and pituitary tumour.

Presentation is similar to that of primary AI. The major distinguishing characteristics are a lack of hyperpigmentation and the absence of mineralocorticoid deficiency; hence hyperkalaemia is not a feature of secondary AI, although hyponatraemia may still be present owing to increased vasopressin levels.

INVESTIGATION OF ADRENAL INSUFFICIENCY

In a stable patient, suspected adrenal insufficiency is routinely investigated by an ACTH stimulation test. The test is performed by administering 250 μg of a synthetic ACTH molecule comprising the first 24 amino acids: tetracosactrin (Synacthen). Plasma total cortisol is measured at 0 and 30 minutes after administration, and a normal response is defined as a peak cortisol measurement over 525 nmol/L.[27] However, it should be noted that current immunoassays exhibit a significant degree of variability, and thus local laboratory reference ranges should be used.[28] The test cannot be performed if the patient is currently being prescribed hydrocortisone as this will cross-react with the assays; *an alternative replacement therapy such as dexamethasone should be used in these cases.*

Secondary AI may be differentiated from primary by a prolonged ACTH test. This is performed by the use of a depot preparation or an intravenous infusion of tetracosactrin for 24–48 hours. Patients with secondary hypoadrenalism show a greater plasma cortisol response at 24 hours than at 4 hours; alternatively, measurement of a baseline ACTH level may be used. In patients with primary AI this will be elevated.

Other biochemical tests that may be used in investigation of AI include the insulin hypoglycaemia test, the overnight metyrapone test and the CRH stimulation test. These investigations are not normally necessary in uncomplicated cases. In addition the use of the low-dose ACTH stimulation test has been advocated, in which only 1 μg of tetracosactrin is used. This approach has not yet gained widespread acceptance.

RELATIVE ADRENAL INSUFFICIENCY

The term *relative adrenal insufficiency* (RAI) was coined to describe a syndrome where the adrenal gland partially responds to stress but the magnitude of response is not commensurate.

Annane et al prospectively studied 189 patients with septic shock and detailed a three-level classification system based upon the basal cortisol level and response

to ACTH.[29] Mortality was found to be highest in those patients with a basal cortisol level above 34 μg/dL (938 nmol/L) and response to ACTH of less than 9 μg/dL (248 nmol/L). Patients with a basal cortisol above 34 μg/dL but a cortisol response greater than 9 μg/dL did better, although the best prognosis was seen in the group with a lower basal cortisol level and high response to ACTH. This pattern of a high basal cortisol and blunted response to ACTH[30–33] is associated with increasing mortality. Although the term 'relative adrenal insufficiency' is often applied to a cortisol response to ACTH of less than 9 μg/dL (248 nmol/L), the changes in glucocorticoid secretion and responsiveness, protein binding, and activity in critical illness have also been described by the terms 'critical-illness-related corticosteroid insufficiency' (CIRCI).[34] The significance of this observation is not clear, however. It has been suggested either to represent a partially suppressed adrenal axis, implying a role for cortisol replacement therapy, or to indicate an 'overstressed' axis, in which case steroid treatment would be inappropriate. Treatment of septic patients fulfilling RAI criteria with hydrocortisone has been shown to improve outcome in only one study,[35] but these results have not been widely accepted (see below). Alternative diagnostic criteria relying on baseline plasma cortisol levels without ACTH stimulation have been proposed,[36] but the lack of a consistently observed relationship between cortisol levels and mortality means that the optimal diagnostic criteria for RAI remain controversial (**Box 61.3**). Possible explanations for the difficulties in assessing adrenal function in this patient group include spontaneous fluctuations in the measured cortisol values,[37] increased variability of assays[28] and changes in CBG levels affecting free cortisol values.[10,38] Measurement of the free cortisol fraction, representing the bioavailable active hormone, has been the focus of recent research interest, with some evidence suggesting it may give a more accurate representation of adrenal function.[10,38] However, the superiority of free cortisol estimations is by no means clear[16,39] and the limited availability of the assay means the test is not in general clinical use.

An alternative hypothesis put forward to explain the constellation of adrenocortical changes in critical illness is a sick euadrenal syndrome analogous of the sick euthyroid state,[40] in which changes in the free cortisol fraction, intracellular cortisol : cortisone interconversion, glucocorticoid receptor density and gene transcription may all act to affect adrenal function at a tissue level. The complexity of this system suggests that simple measurement of total plasma cortisol levels may give only a partial insight into the true functioning of the 'stress response' in the critically ill.

STEROID THERAPY IN CRITICAL ILLNESS

Steroids have an established role in the management of a number of critical illnesses as outlined in **Box 61.4**.

Box 61.3 Controversies in the diagnosis of adrenal insufficiency in the critically ill

1. Limitations of a random cortisol
   a. In the critically ill there is a marked fluctuation in plasma cortisol concentration limiting the utility of a random cortisol[37]
   b. The 'normal' range of cortisol in critical illness is not defined
   c. There is no consensus 'cut-off' value below which adrenal insufficiency is present
2. Limitations of total cortisol
   a. Free cortisol is the bioactive fraction of cortisol
   b. There is large variation in total cortisol assay results when the same specimen is tested in different laboratories and using different assays[28]
   c. Peripheral tissue-specific glucocorticoid resistance is not tested
3. Limitations of the conventional Synacthen test
   a. The HDSST results in plasma Synacthen concentrations that are supraphysiological
   b. Published data may have overestimated the incidence of adrenal insufficiency as many studies have not excluded patients who received etomidate.
   c. The low-dose SST may be a better predictor of outcome

HDSST=high-dose short Synacthen test; SST=short Synacthen test.

Box 61.4 Proven role for steroids in critical illness

1. Addisonian crisis
2. Anaphylaxis
3. Asthma
4. Bacterial meningitis
5. COPD with acute respiratory failure
6. Croup
7. Hypercalcaemia
8. Fulminant vasculitis
9. Idiopathic thrombocytopenic purpura
10. Myasthenic crisis
11. Myxoedema coma
12. Organ transplantation
13. *Pneumocystis carinii* pneumonia
14. Thyroid storm

However, their use in other conditions has not been without controversy.

SPINAL INJURY

Following the publication of the NASCIS II and III trials, high-dose methylprednisolone has been advocated in the management of patients with spinal cord injury. The major criticism of these studies is the lack of a demonstrable improvement in the primary outcome measures. For a more detailed review of the use of steroids in spinal cord injury, the reader is referred to Chapter 78.

HEAD INJURY

The role of steroids in the management of cerebral oedema secondary to tumours is well documented and accepted. However, their role in the management of head injury has been the subject of intense debate. Several prospective studies have not been able to prove any benefit with steroids in head trauma. However, these studies were not adequately powered to detect a difference. The recent CRASH trial with nearly 10 000 patients clearly demonstrated the lack of any benefit with steroids in head injury.[41]

However, a more recent study of multiple trauma suggested that patients fulfilling criteria for CIRCI had a lower rate of development of ventilator-associated pneumonia when treated with hydrocortisone,[42] and these findings were more marked in patients with head injury. This study is awaiting replication.

ACUTE RESPIRATORY DISTRESS SYNDROME (ARDS)

The ARDS clinical trial network published the results of its multicentre study where corticosteroids were administered to patients with ARDS persisting beyond 7 days. Although steroid use was associated with earlier ventilatory wean, improved arterial oxygenation and increased respiratory compliance, there was a higher rate of return to assisted ventilation and neuromuscular weakness.[43] No overall mortality difference was demonstrable between steroid and placebo groups. Commencement of steroids more than 2 weeks after onset of ARDS led to almost a fourfold increase in mortality compared with the placebo group. Consequently, steroids cannot be routinely recommended for persistent ARDS and may be harmful in late-stage ARDS. Although one randomised controlled trial demonstrated some benefit in early ARDS, trial design issues preclude widespread application of these results.[44] Steroids were also not found to be of benefit in ARDS associated with severe H1N1 pneumonia.[45]

SEPTIC SHOCK

Since the first reported use of steroids in sepsis in 1951, therapy with this drug has undergone several transformations, from 'steroid success' in sepsis and malaria in the 70s and early 80s, to 'steroid excess' (30 mg/kg methylprednisolone) in severe sepsis in the mid to late 80s, to total abandonment in the early 90s, and finally a resurgence of its use in the new millennium. The results of the only prospective randomised trial of steroids in septic shock, by Annane et al,[35] which found a beneficial effect, have not been widely accepted owing to problems of randomisation, change of protocol and the use of etomidate (an adrenal suppressant drug) in the study. A European multicentre randomised trial of steroids in septic shock (CORTICUS),[46] did not demonstrate a mortality difference between steroids and placebo. Neither the CORTICUS trial (n=499) nor the French study[35] (n=299) had adequate statistical power to demonstrate a clinically significant reduction in mortality. A recent meta-analysis[47] of 17 trials with 2138 patients reported reduced mortality in patients with septic shock treated with hydrocortisone. These conflicting data mean that the role of glucocorticoid treatment in the management of septic shock is still uncertain, and the Surviving Sepsis Campaign Guidelines of 2008 have downgraded their support for the use of low-dose hydrocortisone in septic shock (weak, low-grade recommendation) in the most recent revision.[48] Currently an ANZICS CTG-driven large multicentre randomised controlled trial (ADRENAL) of hydrocortisone in septic shock is under way (clinical trials.gov NCT01448109).

The role of fludrocortisone in septic shock also remains controversial. The study by Annane at al, quoted above, included a dose of 50 μg of fludrocortisone administered orally.[35] It has been argued, however, that doses of cortisol above 50 mg a day provide sufficient mineralocorticoid cover, and thus separate supplementation is unnecessary.[26]

Furthermore, the oral route of administration is unreliable in critically ill patients. A study comparing fludrocortisone plus hydrocortisone with hydrocortisone alone in septic patients failed to demonstrate a difference in outcome.[49]

PNEUMONIA

Adjunctive treatment with glucocorticoids has been advocated in the management of pneumonia as a strategy to reduce systemic effects of locally produced pulmonary cytokines, although results from these studies have been conflicting. A pilot study reported an improvement in oxygenation and mortality in patients with severe pneumonia treated with 7 days of hydrocortisone.[50] A larger trial in community-acquired pneumonia reported a reduced length of stay in patients receiving a 4-day course of dexamethasone; however, only 5% of these patients required ICU care.[51] Conversely, a trial of 7 days of prednisolone treatment in patients with community-acquired pneumonia showed no evidence of efficacy in either cure rate or length of stay,[52] and a recent observational study of 316 patients with ICU-acquired pneumonia suggested that systemic steroid treatment was associated with an increase in mortality.[53] At present, glucocorticoid treatment is not routinely recommended for critically ill patients with pneumonia; an exception would be for the case of *Pneumocystis jirovecii* infection in patients suffering from human immunodeficiency virus (HIV).[54]

MENINGITIS

Randomised controlled trials have demonstrated the benefit of early steroid therapy in paediatric meningitis, particularly with *H. influenzae* infections. There is also

Box 61.5 Side-effects of corticosteroid therapy

Adrenal suppression	Hypertension
Hypokalaemia	Osteoporosis
Glucose intolerance	Peptic ulcer disease
Truncal obesity	Glaucoma
Myopathy	Hyperlipidaemia
Mood alterations including psychosis	Aseptic necrosis of femoral/humeral head

evidence of benefit in adult patients with meningitis, particularly with pneumococcal infections. (For more detail refer to Ch. 54.)

SIDE-EFFECTS OF STEROID THERAPY

Steroid therapy is associated with numerous side-effects. Those that would be of particular relevance to intensive care are (a full list is given in **Box 61.5**):

- *suppression of the adrenal axis (discussed above):* patients who have been receiving steroid treatment for less than a week are unlikely to be affected
- *hyperglycaemia:* this may be associated with adverse outcomes in critically ill patients[55]
- *myopathy:* steroid therapy is known to be associated with muscle weakness and also shown to be an independent risk factor for developing ICU-acquired muscle paresis; this has significant clinical implications for weaning patients from mechanical ventilation
- *hypokalaemia*
- *leucocytosis:* corticosteroids increase the neutrophil count by a shift from the marginating to the circulating pool; this effect may lead to concerns that the patient has developed an occult infection
- *poor wound healing*
- *immunosupression*
- *pancreatitis.*

Acute calcium disorders

Balasubramanian Venkatesh

Calcium is an important cation and the principal electrolyte of the body. A total of 1–2 kg is present in the average adult, of which 99% is found in the bone. Of the remaining 1%, nine-tenths are present in the cells and only a tenth in the extracellular fluid. In the plasma, 50% of the calcium is ionised, 40% bound to plasma proteins, mainly to albumin, and the remaining 10% is chelated to anions such as citrate, bicarbonate, lactate, sulphate phosphate and ketones. The chelated fraction is usually of little clinical importance, but is increased in conditions where some of these anionic concentrations might be elevated, as in renal failure. Whereas most calcium inside the cell is in the form of insoluble complexes, the concentration of intracellular ionised calcium is about 0.1 μmol/L, creating a gradient of 10 000 : 1 between plasma and intracellular fluid (ICF) levels of ionised calcium.[1] A schematic illustration of calcium distribution within the various body compartments is shown in **Figure 62.1**.

Because ionised calcium is the biologically active component of ECF calcium with respect to physiological functions (**Box 62.1**) and is also the reference variable for endocrine regulation of calcium homeostasis, its measurement is recognised as being one of prime importance in the management of disorders of calcium homeostasis.

HORMONAL REGULATION OF CALCIUM HOMEOSTASIS

The concentration of ionised calcium in the plasma is subject to tight hormonal control, particularly parathyroid hormone (PTH). A G-protein coupled calcium receptor plays a significant role in the maintenance of calcium homeostasis. This receptor, responsible for sensing extracellular calcium concentration, is present on the cell membrane of the chief cells of the parathyroid and in bone, gut and the kidney. In response to ionised hypocalcaemia, PTH secretion is stimulated, which in turn serves to restore serum calcium levels back to normal by increasing osteoclastic activity in the bone and renal reabsorption of calcium and stimulating renal synthesis of 1,25(OH)D_3 (calcitriol – the active metabolite of vitamin D), which increases gut absorption of calcium.

Calcitriol production is stimulated by hypocalcaemia, and vice versa. Calcitriol increases serum calcium by largely promoting gut reabsorption, and to a lesser extent renal reabsorption of calcium.

Calcitonin, a hypocalcaemic peptide hormone, produced by the thyroid, acts as a physiological antagonist to PTH. Although calcitonin has been shown to reduce serum calcium levels in animals by increasing renal clearance of calcium and inhibiting bone resorption, its role in humans is less clear. Despite extreme variations in calcitonin levels, for example total lack in patients who have undergone total thyroidectomy, or excess plasma levels, as seen in patients with medullary carcinoma of the thyroid gland, no significant changes in calcium and phosphate metabolism are seen. Calcitonin is useful as a pharmacological agent in the management of hypercalcaemia.

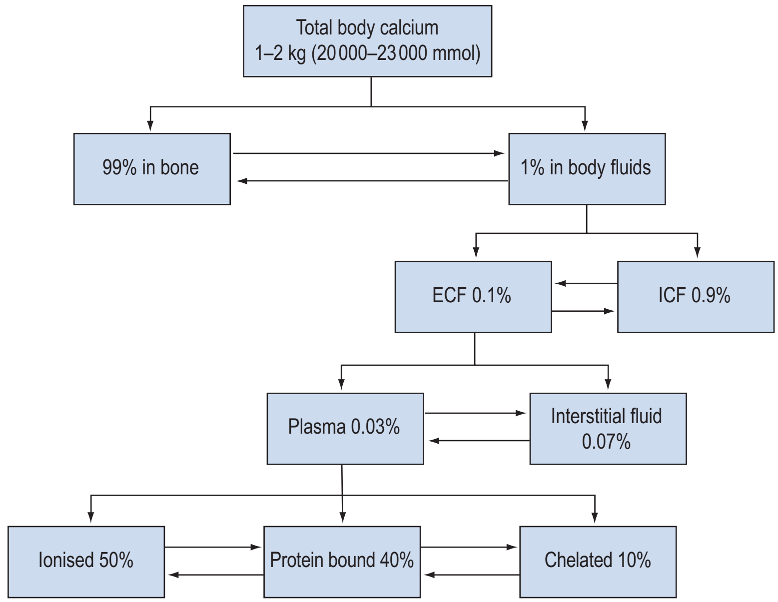
METABOLIC FACTORS INFLUENCING CALCIUM HOMEOSTASIS

Alterations in serum protein, pH, serum phosphate and magnesium closely impact on serum calcium concentrations. Total plasma calcium levels vary with alterations in plasma protein concentration. Several equations have been put forward for the adjustment of serum calcium in the face of alterations in serum protein concentrations. The validity of these equations is dependent upon the patient population, the methodology used for assessment of serum calcium and the reference intervals.[4] Clinicians often use simple rules of thumb – a correction is made for hypoalbuminaemia by adding 0.2 mmol/L to the measured serum calcium concentration for every 10 g/L decrease in serum albumin concentration below normal (40 g/L). The corresponding correction factor for globulins is –0.04 mmol/L of serum calcium for every 10 g/L rise in serum globulin.

Changes in pH alter protein binding of calcium. As the relationship between ionised calcium (iCa) and changes in pH is well defined, iCa concentrations can be predicted for a given pH using the following formula:

$$\text{corrected iCa at pH 7.4} = \text{measured iCa} \times [1 - (0.53 \times (7.40 - \text{measured pH}))]^4$$

Figure 62.1 Distribution of body calcium. ECF = extracellular fluid; ICF = intracellular fluid.



Box 62.1 Functions of calcium[1,15]

- Excitation – contraction coupling in cardiac, skeletal and smooth muscle
- Cardiac action potentials and pacemaker activity
- Release of neurotransmitters
- Coagulation of blood
- Bone formation and metabolism
- Hormone release
- Ciliary motility
- Catecholamine responsiveness at the receptor site[7]
- Strong cation
- Regulation of cell growth and apoptosis

Table 62.1 Daily calcium balance

GASTROINTESTINAL TRACT	
Diet	600–1200 mg/day
Absorbed	200–400 mg/day
Secreted	150–800 mg/day
RENAL	
Filtered	11000 mg/day
Reabsorbed (97% in the proximal convoluted tubule)	10800 mg/day
Urinary calcium	200 mg/day
BONE	
Turnover	600–800 mg/day

Another rule of thumb is that an increase in pH by 0.1 pH units results in a decrease in ionised calcium by approximately 0.1 mmol/L.[5]

Calcium and phosphate are closely linked by the following reaction in the extracellular fluid. $HPO_4^{2-} + Ca^{2+} = CaHPO_4$. Increases in serum phosphate shift the reaction to the right. When the calcium phosphate solubility product exceeds the critical value of 5 mmol/L, calcium deposition occurs in the tissues, resulting in a fall in serum calcium concentration and a secondary increase in PTH secretion. Reductions in phosphate concentration lead to corresponding changes in the opposite direction.

As magnesium is required for PTH secretion and end-organ responsiveness, alterations in serum magnesium have an impact on serum calcium concentration.

Turnover of calcium in the bone is predominantly under the control of PTH and calcitriol, although prostaglandins and some of the cytokines also play a role in it. Bone resorption is mediated by osteoclasts, whereas osteoblasts are involved in bone formation. The daily calcium balance is summarised in **Table 62.1**.

MEASUREMENT OF SERUM CALCIUM

Most hospital laboratories measure total serum calcium. The normal plasma concentration is 2.2–2.6 mmol/L. However, the ionised form (1.1–1.3 mmol/L) is the active fraction and its measurement is not routine in many laboratories, although most state-of-the-art blood gas analysers can measure serum ionised calcium concentrations. Estimation of ionised calcium from total serum calcium concentration using mathematical algorithms is unreliable in critically ill patients.[6–8] Heparin

forms complexes with calcium and decreases ionised calcium.[9] A heparin concentration of <15 units/mL of whole blood is therefore recommended for the measurement of ionised calcium.[10] Anaerobic collection of the specimen is recommended as CO_2 loss from the specimen may result in alkalosis and reduction in ionised calcium concentration. Calcium levels are also reduced by a concomitant lactic acidosis owing to chelation by lactate ion.[11] Free fatty acids (FFAs) increase calcium binding to albumin and may form a portion of the calcium-binding site.[12] Increases in FFAs may be seen in relation to stress, use of steroids, catecholamines and heparin. The impact of pH on calcium measurements has been described above. The normal reference levels of serum calcium are reduced in pregnancy and in the early neonatal period.[13]

HYPERCALCAEMIA IN CRITICALLY ILL PATIENTS

The frequency of hypercalcaemia in critically ill patients is not well established, although it is not as common as hypocalcaemia. Depending on the patient population, the reported incidence ranges from 3–5% to as high as 32%.[14,15] Admission to the ICU with a primary diagnosis of a hypercalcaemic crisis is uncommon. Although a number of aetiologies have been described (**Box 62.2**), in the critical care setting, hypercalcaemic crisis is usually due to malignancy-related hypercalcaemia, renal failure or posthypocalcaemic hypercalcaemia.[16] Before undertaking a work-up for hypercalcaemia, it is important to exclude false-positive measurements. This is usually the result of inadvertent haemoconcentration during venepuncture and elevation in serum protein, although ionised calcium levels are not reported to be affected by haemoconcentration.[17] *Pseudohypercalcaemia* has also been described in the setting of essential thrombocythaemia. The erroneous result is thought to be due to in vitro release of calcium from platelets, analogous to the pseudohyperkalaemia seen in the same condition.[18]

From a pathophysiological standpoint, hypercalcaemia may be due to an elevation in PTH, in which case the homeostatic regulatory and feedback mechanisms are preserved, and this is termed *equilibrium hypercalcaemia*. Alternatively, it could be a non-parathyroid-mediated hypercalcaemia with associated breakdown of homeostatic mechanisms, and this situation is termed *disequilibrium hypercalcaemia*.

Box 62.2 Causes of hypercalcaemia

Common causes of hypercalcaemia in the critically ill patient

Complication of malignancy:
- bony metastases
- humoral hypercalcaemia of malignancy

Posthypocalcaemic hypercalcaemia:
- recovery from pancreatitis[15]
- recovery from acute renal failure following rhabdomyolysis[37–41]

Primary hyperparathyroidism
Adrenal insufficiency[23,24]
Prolonged immobilisation[18–21]
Disorders of magnesium metabolism
Use of TPN[42]
Hypovolaemia
Iatrogenic calcium administration

Less common causes of hypercalcaemia in the critically ill patient

Granulomatous diseases – sarcoidosis, tuberculosis, berylliosis
Vitamin A and D intoxication
Multiple myeloma
Endocrine:
- thyrotoxicosis
- acromegaly
- phaeochromocytoma

Lithium – chronic therapy
Tamoxifen
Rare association between drugs and hypercalcaemia
Theophylline, omeprazole and growth hormone therapy

MECHANISMS OF HYPERCALCAEMIA

Malignancy-related hypercalcaemia might arise from bony metastases or humoral hypercalcaemia of malignancy. In the latter (seen with bronchogenic carcinoma and hypernephroma), tumour osteolysis of bone resulting from the release of PTH-like substances (which cross-react with PTH in the radioimmunoassay, but are not identical to PTH), calcitriol, osteoclast-activating factor and prostaglandins are thought to be the major underlying mechanisms. Aggravating factors include dehydration, immobilisation and renal failure.

Posthypocalcaemic hypercalcaemia is a transient phenomenon seen in patients following a period of hypocalcaemia.[16] This has been attributed to a parathyroid hyperplasia that develops during the period of hypocalcaemia, which results in a rebound hypercalcaemia following resolution of the underlying hypocalcaemic disorder.

Immobilisation hypercalcaemia results from an alteration in balance between bone formation and resorption.[19–22] This leads to loss of bone minerals, hypercalcaemia, hypercalciuria and increased risk of renal failure. In patients with normal bone turnover, immobilisation rarely causes significant hypercalcaemia. However, in patients with rapid turnover of bone (children, post-fracture patients, hyperparathyroidism, Paget's disease, spinal injuries and Guillain–Barré syndrome), this may result in severe hypercalcaemia.

Intravascular volume depletion reduces renal calcium excretion by a combination of reduced glomerular filtration and increased tubular reabsorption

of calcium. Hypercalcaemia further compounds this problem by causing a concentrating defect in the renal tubules, thus creating a polyuria and further aggravating the hypovolaemia. Extrarenal production of calcitriol by lymphocytes in granulomata is thought to be the predominant mechanism of hypercalcaemia in granulomatous diseases.[23,24] Only 10–20% of patients with adrenal insufficiency develop hypercalcaemia.[25,26] The aetiology of this is thought to be multifactorial: intravascular volume depletion, haemoconcentration of plasma proteins and the loss of anti-vitamin D effects of glucocorticoids. Hypercalcaemia can be associated with the use of certain medications – vitamin D toxicity, loop diuretics, thiazide diuretics and lithium. For rarer causes of hypercalcaemia, the reader is referred to the reviews by Kallas et al and Jacobs & Bilezikian.[23,27]

MANIFESTATIONS OF HYPERCALCAEMIA

The clinical manifestations of hypercalcaemia (commonly encountered when total serum calcium exceeds 3 mmol/L) are outlined in **Box 62.3**. *Hypercalcaemic crisis* is defined as severe hypercalcaemia (total serum Ca >3.5 mmol/L) associated with acute symptoms and signs.

INVESTIGATIONS

A detailed diagnostic algorithm is outside of the scope of this chapter. The basic work-up should include serum calcium, phosphorus and alkaline phosphatase estimation, PTH assay, renal function assessment and a skeletal survey.

Box 62.3 Clinical manifestations of hypercalcaemia*

Cardiovascular
Hypertension
Arrhythmias
Digitalis sensitivity
Catecholamine resistance

Urinary system
Nephrocalcinosis
Nephrolithiasis
Tubular dysfunction
Renal failure

Gastrointestinal
Anorexia/nausea/vomiting
Constipation
Peptic ulcer
Pancreatitis

Neuromuscular
Weakness

Neuropsychiatric
Depression
Disorientation
Psychosis
Coma
Seizures

*Ectopic calcification is usually seen with chronic hypercalcaemia.

THERAPY OF HYPERCALCAEMIA AND HYPERCALCAEMIC CRISIS

Mild asymptomatic hypercalcaemia does not require emergent treatment. Therapy is usually directed at the underlying cause. The management of hypercalcaemic crisis consists of two principal components:

1. Increasing urinary excretion of calcium
2. Reducing bone resorption.

INCREASING URINARY EXCRETION OF CALCIUM

As almost all patients with hypercalcaemia are volume-depleted, the initial therapy consists of rehydration with normal saline, followed by diuresis with furosemide. Rehydration with normal saline improves intravascular volume, reducing serum calcium by extracellular dilution, and saliuresis promotes calcium loss in the urine. Volume expansion should be titrated to clinical end-points and CVP monitoring. A urine output of 4–5 L should be aimed for in these patients to promote calciuresis. In many patients, these measures would achieve a reduction in serum calcium by about 0.4–0.5 mmol/L. Hypokalaemia, hypomagnesaemia and calcium stone formation in the urine are potential side-effects of this mode of treatment.

In patients with established renal failure, in whom forced diuresis cannot be instituted, dialysis against a dialysate with zero or low calcium concentrations should be the treatment of choice.

REDUCTION OF BONE RESORPTION

Measures to increase urinary excretion of calcium should be followed up with administration of agents that minimise bone resorption. A number of agents are available and these are listed in **Table 62.2**. Disodium EDTA at a dose of 15–50 mg/kg i.v. rapidly lowers serum calcium. However, its propensity to reduce serum calcium rapidly coupled with its nephrotoxic effects limits its usefulness to life-threatening hypercalcaemia. Other therapeutic modalities include the use of NSAIDs and parathyroidectomy. Calcimimetics are agents that increase the activation of the calcium receptor thus reducing serum PTH concentrations. Cinacalcet is a first-generation calcimimetic, which has shown promise in early randomised trials for the management of hypercalcaemia; it has also been shown to be effective in the management of primary hyperparathyroidism across a wide spectrum of disease severity.[28] However, its role in the management of acute hypercalcaemia[29] is limited.

At the present time, several newer and more potent bisphosphonates are under development. Their efficacy combined with a relative lack of side-effects

Table 62.2 Therapeutic agents for reducing bone resorption

THERAPY	INDICATIONS	DOSE	ONSET TIME/ DURATION	LIMITATIONS	MECHANISM OF ACTION	COMMENTS
Bi-Phosponates* Etidronate (first-generation)	Malignancy-related hypercalcaemia	5 mg/kg per day	1–2 days, lasts 5–7 days	Hyperphosphataemia, short duration of action	Inhibit osteoclast activity, may have some effect on osteoblasts	High-potency group. Pamidronate lowers Ca levels more rapidly than etidronate
Pamidronate (second-generation)		90 mg as an infusion every 4 weeks	1–2 days, lasts 10–14 days	Hypophosphataemia, fever and hypomagnesaemia		
Calcitonin	Hypercalcaemia, Paget's disease	Initial IV dose 3–4 U/kg followed by 4 U/kg s.c. 12-hourly	Hours, lasts 2–3 days	Nausea, abdominal pain, flushing, tachyphylaxis, limited efficacy	Inhibit osteoclast activity, reduces renal tubular reabsorption of calcium	Tachyphylaxis minimised by concomitant steroid therapy
Glucocorticoids	Vitamin D toxicity, myeloma, lymphoma, granulomata	i.v. hydrocortisone 200–400 mg/day	Days, lasts days to weeks	Glucocorticoid side-effects	Inhibit inflammatory cell production of calcitriol, reduce gut absorption of calcium	Improve the efficacy of calcitonin
Gallium nitrate	Malignancy-related hypercalcaemia	100–200 mg/m^2 per day for 5–7 days	5–6 days, lasts 7–10 days	Nephrotoxic	Inhibits bone resorption and alters bone crystal structure	Recent phase II data suggest equivalent efficacy with pamidronate[45]
Plicamycin	Malignancy-related hypercalcaemia	25 μg/kg i.v.	Rapid onset, lasts for a few days	Hepatotoxic, nephrotoxic and thrombocytopoenia	Inhibits cellular RNA synthesis	Side-effect profile limits the use of this drug
Intravenous phosphates	Limited clinical role	10–15 mmol as an infusion repeated at regular intervals	Hours, lasts 24–48 hours after cessation	Ectopic calcification, severe hypocalcaemia	Ectopic calcification, reduce gut absorption, inhibition of bone resorption	Use superseded by the other modalities described

*Other biphosphonates include ibandronate, risedronate and zoledronate. As compared to pamidronate, zoledronate has the advantage of simplicity of administration and better control of hypercalcemia.
i.v., intravenous; s.c., subcutaneous.

make them the agents of choice for the treatment of malignancy-related hypercalcaemia. Other drugs that have been used in the management of hypercalcaemia include prostaglandin inhibitors for cancer-related hypercalcaemia, ketoconazole and chloroquine (for sarcoid-induced hypercalcaemia).[24]

ADJUNCTIVE MEASURES IN THE MANAGEMENT OF HYPERCALCAEMIA

Monitoring of cardiorespiratory function and biochemical status is mandatory during therapy of hypercalcaemia. Thiazide diuretics, vitamin D and absorbable antacids should be avoided. Hypercalcaemia potentiates digitalis effect and dosage should be adjusted accordingly. Endocrinologists should be consulted for further management.

HYPOCALCAEMIA

Hypocalcaemia is more common than hypercalcaemia in critically ill patients, with an estimated incidence of around 70–90%.[16] As the ionised calcium is the biologically active moiety, it is important to look at ionised hypocalcaemia. The frequency of this is far more varied, ranging from 15 to 70%.[16,30,31] *Spurious hypocalcaemia* is seen with poor storage of specimens prior to analysis, resulting in CO_2 loss from the specimen, use of EDTA or large doses of heparin as anticoagulants in the syringe. Gadodiamide used in association with MRI as a contrast medium can interfere with the colorimetric assay and cause spurious hypocalcaemia.[32]

AETIOLOGIES

The aetiology of ionised hypocalcaemia based on the predominant pathophysiological mechanism is listed in **Box 62.4**. The other contributory mechanisms of hypocalcaemia in each of the conditions are shown in brackets.

Although a long list of causes exists for hypocalcaemia, calcium chelation and hypoparathyroidism constitute the common mechanisms of ionised hypocalcaemia in intensive care. The increasing prevalence of citrate anticoagulation used for renal replacement therapy, if not accompanied by appropriate metabolic monitoring, could emerge as another cause of hypocalcaemia in critically ill patients. Frequently, hypocalcaemia is accompanied by a number of other biochemical abnormalities, thus a pattern recognition approach towards the cause of hypocalcaemia will point to its aetiology and save a considerable amount of investigations for the patient. Common diagnostic patterns are listed below in **Table 62.3**.

Although alkalosis is frequently associated with ionised hypocalcaemia, the presence of a metabolic acidosis in the face of low serum ionised calcium narrows the differential diagnosis even further (**Box 62.5**).

Box 62.4 Aetiology of ionised hypocalcaemia

Calcium chelation
- Alkalosis (increased binding of calcium by albumin)
- Citrate toxicity (calcium chelation)
- Hyperphosphataemia (calcium chelation, ectopic calcification, reduced vitamin D3 activity)
- Pancreatitis (calcium soap formation, reduced parathyroid secretion)
- Tumour lysis syndrome (hyperphosphataemia)
- Rhabdomyolysis (hyperphosphataemia and reduced levels of calcitriol)

Hypoparathyroidism
- Hypo- and hypermagnesaemia
- Sepsis (decrease PTH secretion, calcitriol resistance, intracellular shift of calcium)
- Burns (decrease in PTH secretion)
- Neck surgery (removal of parathyroid gland, calcitonin release during thyroid surgery and hungry bone syndrome post-parathyroidectomy)

Hypovitaminosis D
- Inadequate intake
- Malabsorption
- Liver disease (impaired 25-hydroxylation of cholecalciferol)
- Renal failure (impaired 1-hydroxylation of cholecalciferol, hyperphosphataemia)

Reduced bone turnover
- Osteoporosis
- Elderly
- Cachexia

Drug induced
- Phenytoin (accelerated metabolism of vitamin D3)
- Diphosphonates (see under hypercalcaemia)
- Propofol
- EDTA (calcium chelation)
- Ethylene glycol (formation of calcium oxalate crystals in the urine
- Cis-platinum (renal tubular damage leading to hypermagnesuria)
- Protamine
- Gentamicin (hypermagnesuria leading to hypomagnesaemia and therefore hypocalcaemia)

CLINICAL MANIFESTATIONS OF HYPOCALCAEMIA

Mild degrees of hypocalcaemia are usually asymptomatic. Ionised calcium levels less than 0.8 mmol/L may cause neuromuscular irritability and result in clinical symptoms. The clinical manifestations of hypocalcaemia are summarised in **Box 62.6**. The manifestations listed in Box 62.6 are by no means a comprehensive list of all the clinical features, but include the ones most commonly seen in the critical care setting.

When eliciting tetany, Trousseau's sign (carpopedal spasm) is more specific for hypocalcaemia than is Chvostek's sign (facial twitch in response to facial nerve stimulus, which is present in 10–30% of the normal population). ECG changes do not correlate well with

Table 62.3 Pattern recognition in the diagnosis of common causes of hypocalcaemia

AETIOLOGY OF HYPOCALCAEMIA	CLINICAL/BIOCHEMICAL PATTERNS
Low serum albumin	Reduced total calcium, normal ionised calcium
Alkalosis	Normal total calcium, reduced ionised calcium
Hypomagnesaemia	Reduced ionised calcium and hypokalaemia
Pancreatitis	Hypocalcaemia, elevated serum lipase and glucose
Renal failure	Elevated blood urea nitrogen, elevated phosphate
Rhabdomyolysis	Hypocalcaemia, elevated phosphate, creatine kinase and urinary myoglobin
Tumour lysis syndrome	Hypocalcaemia, elevated phosphate, potassium and urate

Box 62.5 Hypocalcaemia with metabolic acidosis

Acute renal failure
Tumour lysis
Rhabdomyolysis
Pancreatitis
Ethylene glycol poisoning
Hydrofluoric acid intoxication

Box 62.6 Clinical manifestations of hypocalcaemia

Central nervous system
Circumoral and peripheral paraesthesia
Muscle cramps
Tetany
Seizures
Extrapyramidal manifestations: tremor, ataxia, dystonia
Proximal myopathy
Depression, anxiety, psychosis
Cardiovascular
Arrhythmias
Hypotension, inotrope unresponsiveness
Prolonged QT intervals, T-wave inversion
Loss of digitalis effect
Respiratory
Apnoea
Laryngospasm
Bronchospasm

Table 62.4 Commonly used i.v. calcium preparations

PREPARATION	DOSAGE (ML)	ELEMENTAL CALCIUM/GRAM
Calcium gluconate	10	93 mg (2.3 mmol)
Calcium chloride	10	272 mg (6.8 mmol)
Calcium acetate	10	253 mg (6.35 mmol)

the degree of hypocalcaemia. The symptoms of hypocalcaemia are exacerbated by a coexisting hypokalaemia and a hypomagnesaemia.

The laboratory work-up should include serum calcium, phosphorus, magnesium and alkaline phosphatase, PTH and vitamin D assays and renal function assessment.

APPROACH TO THE TREATMENT OF ASYMPTOMATIC AND SYMPTOMATIC HYPOCALCAEMIA

ARGUMENTS FOR AND AGAINST CORRECTION OF ASYMPTOMATIC HYPOCALCAEMIA

As stated before, it is not clear if asymptomatic hypocalcaemia needs correction. Based on published data which suggest that critical care hypocalcaemia is associated with a higher mortality and increased length of stay in intensive care,[33–35] it is advocated that ionised hypocalcaemia be corrected routinely irrespective of the level. However, arguments exist against the routine correction of asymptomatic ionised hypocalcaemia. Increases in cytosolic calcium lead to disruption of intracellular processes, activation of proteases and can lead to ischaemia and reperfusion injury.[36] Also, there are data suggesting that ionised calcium is an important participant in the pathogenesis of coronary and cerebral vasospasm.[37] In rodent models of endotoxic shock, there are also data demonstrating an increased mortality when these rats were administered intravenous calcium.[38] Most clinicians agree that an ionised calcium level of <0.8 mmol/L needs correction even if asymptomatic.

MANAGEMENT OF ACUTE SYMPTOMATIC HYPOCALCAEMIA

Acute symptomatic hypocalcaemia is a medical emergency that requires immediate therapy. In addition to treatment of underlying cause and support of airway, breathing and circulation, the definitive treatment includes administration of intravenous calcium. Intravenous calcium is available as a calcium salt of chloride or gluconate or acetate. The main difference between these formulations is the amount of elemental calcium available at equivalent volumes of drug (**Table 62.4**). The dose of calcium required should be based on the elemental calcium.[39] Intravenous calcium can be administered as a bolus or as an infusion. Rapid administration of calcium may cause nausea, flushing, headache

Box 62.7 Indications for calcium administration

Absolute
Symptomatic hypocalcaemia
Ionised Ca <0.8 mmol/L
Hyperkalaemia
Ca channel blocker overdose
Relative
β-blocker overdose
Hypermagnesaemia
Hypocalcaemia in the face of high inotrope requirement
Massive blood transfusion post cardiopulmonary bypass to augment cardiac contractility

and arrhythmias. Digitalis toxicity may be precipitated. Extravasation of calcium may lead to tissue irritation, particularly with the chloride salt. Calcium chloride may be better than calcium gluconate for the management of hypocalcaemia, if there is concomitant alkalosis. Following an initial bolus, an infusion may be commenced at a rate of 1–2 mg/kg/h of elemental calcium to maintain target levels of ionised calcium. With correction of the underlying disorder and restoration of calcium to normal levels, the infusion can be tapered and stopped. Adequacy of calcium therapy can be monitored clinically and by performing serial determinations of ionised calcium. Failure of ionised calcium to increase after commencement of i.v. calcium may indicate an underlying magnesium deficiency. This can be corrected by administration of 10 mmol of intravenous magnesium over 20 minutes.

Administration of calcium in the setting of hyperphosphataemia may result in calcium precipitation in the tissues. In these situations, a phosphate binder may be administered. Calcium salts should not be administered with bicarbonate since the two precipitate. The other indications for calcium administration are listed in **Box 62.7**. Other therapy for hypocalcaemia consists of oral calcium supplements and calcitriol administration, although these are usually used in the management of chronic hypocalcaemia.

ASSOCIATION BETWEEN IONISED CALCIUM CONCENTRATION AND OUTCOME IN CRITICAL ILLNESS

A recent retrospective study examined the association between serum ionised calcium (iCa) and mortality in a heterogeneous cohort of critically ill patients.[40] Data from >7000 patients generating >175 000 iCa measurements were analysed. The investigators concluded that, within a broad range of values, ionised calcium concentration has no independent association with hospital or intensive care unit mortality. However, from multivariate logistic regression analysis, an ionised calcium <0.8 mmol/L or an ionised calcium >1.4 mmol/L was independently associated with intensive care unit and hospital mortality. In patients requiring massive blood transfusion, another study reported a concentration-dependent effect of hypocalcaemia on mortality.[41]

VITAMIN D AND CRITICAL ILLNESS

The traditional role of vitamin D has been thought to be the maintenance of adequate serum calcium and phosphate levels, for bone mineralisation and optimal cardiac and skeletal muscle function. Over the past decade, data from biochemical and molecular genetic studies indicate that vitamin D has a much wider range of effects than this traditional role. These non-skeletal effects, termed pleiotropic, include potentiation of antimicrobial action, modification of inflammation, cardioprotective effects and immunomodulatory effects. Several large observational studies have demonstrated an association between increased morbidity and mortality and lower vitamin D levels as measured by serum $25(OH)D_3$ in critically ill patients. On the other hand there are data to suggest that a single measurement of vitamin D may not be reflective of the 24-hour profile in critically ill patients owing to the marked variability.[42,43] Moreover there are also data to suggest that $1,25(OH)D_3$ levels may be increased during the inflammatory response. Currently, the existing data are insufficient to make an evidence-based recommendation regarding its potential benefit in the ICU.[44] Results from large prospective randomised controlled trials are lacking.

Preeclampsia and eclampsia

Wai Ka Ming and Tony Gin

Pre-eclampsia is a syndrome specific to pregnancy. Although diagnostic criteria have varied among countries and over time, it is generally defined as new onset of hypertension and proteinuria after 20 weeks' gestation (**Table 63.1**). In Australian practice, pre-eclampsia is defined as new-onset hypertension after 20 weeks' gestation with organ involvement; proteinuria is not mandatory for establishing the clinical diagnosis.[1] Many organisations have issued extensive national guidelines for the prevention, diagnosis and treatment of pre-eclampsia and other hypertensive disorders in pregnancy.[1–5] Eclampsia describes the occurrence in a pre-eclamptic woman of seizures not attributable to other causes.

Pre-eclampsia complicates 2–10% of pregnancies worldwide.[6] In the United Kingdom, the maternal mortality attributed to pre-eclampsia in 2006–2008 was 0.83 per 100 000 deliveries.[7] In developed countries, eclampsia complicates 2–3 cases per 10 000 deliveries with mortality less than 1%.[8] Despite the decline of maternal mortality from pre-eclampsia and related complications in developed countries over the past two decades, hypertensive disorders remain one of the three leading cause of maternal death. The incidence of eclampsia and maternal mortality are higher in developing countries.[9] This may be related to poor antenatal care services, and lack of expertise and health care resources.[10]

Factors associated with increased maternal risk include:[11,12]

- onset at or less than 32 weeks' gestation
- greater maternal age and parity
- pre-existing hypertension or medical complications
- Afro-Caribbean descent
- nausea and vomiting and epigastric pain
- abnormal laboratory tests, including raised liver enzymes, increased serum creatinine and increased serum uric acid.

Patients may be referred to the intensive care unit (ICU) for poorly controlled hypertension, convulsions, postoperative care, or following complications such as pulmonary oedema, renal failure, haemorrhage, coagulopathy and stroke.

AETIOLOGY

The cause of pre-eclampsia is unknown, and there is no satisfactory single unifying hypothesis. Pre-eclampsia is more common in primigravidae, multiple gestation, obesity, African–American race, molar pregnancy, pre-existing hypertension, underlying disease (e.g. autoimmune disease, renal disease, diabetes and thrombophilia) and previous or family history of pre-eclampsia.[13] Although there is a genetic predisposition, no particular gene or mode of inheritance has been strongly implicated. Pre-eclampsia may be a result of cumulative effects of variants at multiple genes, both fetal and maternal.[14–15] Genetic factors could influence not only the aetiology of pre-eclampsia, but also the development of the disease and response to treatment. Some investigators differentiate early-onset (before 34 weeks' gestation) and late-onset pre-eclampsia (at or after 34 weeks) because of differences in outcomes, biochemical markers and clinical features.[16]

PATHOGENESIS

Pre-eclampsia is a systemic disease that affects most organ systems. Many theories of pathogenesis have been proposed, but a common concept is that of a two-stage disease with an initial stage of abnormal placentation and placental ischaemia, followed by a second stage of clinical disease. Initially, there is inadequate endovascular invasion of fetal trophoblast into the spiral arteries with reduced dilatation of uterine spiral arteries and placental hypoxia. This acts as a precipitating factor that leads to an imbalance of angiogenic and antiangiogenic factors and a generalised inflammatory response. The exact link between placental triggering and the systemic response is unknown, but there is placental release of circulating antiangiogenic factors such as soluble Fms-like tyrosine kinase-1 (sFlt1) and soluble endoglin, and inflammatory cytokines. There are reduced concentrations of angiogenic factors such as vascular endothelial growth factor and placental growth factor.[17] All this leads to diffuse endothelial dysfunction with an increase in sensitivity to vasoactive

Table 63.1 Basic diagnostic criteria for pre-eclampsia

Hypertension *and*	Systolic arterial pressure >140 mmHg (18.6 kPa) *or* Diastolic arterial pressure* >90 mmHg (12 kPa) >/=300 mg protein in a 24-hour collection** *or*
Proteinuria	Random urine protein/ creatinine >/=30 mg/mmol

*Korotkoff phase V.
A rise in blood pressure above baseline and oedema are now not usually included.
**A positive dipstick test for proteinuria should be confirmed by 24-hour urine collection.

substances and activation of a key vasoconstrictor endothelin-1,[18] a decrease in endothelial synthesis of vasodilator substances such as prostaglandin and nitric oxide, activation of platelets and coagulation, and an increase in capillary permeability. This then causes widespread vasoconstriction, fluid extravasation, proteinuria, decreased intravascular volume, haemoconcentration and decreased organ perfusion.

CLINICAL PRESENTATION

Pre-eclampsia is a syndrome with a spectrum of presentations. Although hypertension is the cardinal sign, some women present with convulsions, abdominal pain or general malaise and some complications may be life-threatening without a marked increase in blood pressure. Features typical of severe disease are listed in **Table 63.2**. Rarely, cocaine intoxication and phaeochromocytoma may be confused with pre-eclampsia.

Haemodynamic changes of pre-eclampsia consist of hypertension, increased systemic vascular resistance and decreased intravascular volume. Cardiac output is often decreased, usually secondary to changes in preload and afterload rather than contractility.[19] Sympathetic activation occurs, and this may account for observations of increased cardiac output in the early stage.[20] However early-onset and late-onset pre-eclampsia appear to have different patterns of cardiovascular change.[21]

Pulmonary oedema may occur because of iatrogenic fluid overload, decreased left ventricular function, increased capillary permeability and narrowing of the colloid osmotic–pulmonary capillary wedge pressure gradient; this is more likely to occur after delivery. Sudden ventricular tachycardia may occur during hypertensive crises.

Neurological complications include eclamptic convulsions, cerebral oedema and stroke. Intracranial haemorrhage is an important cause of death. In recent decades, posterior reversible encephalopathy syndrome has been recognised as a primary event in eclampsia.[22]

Table 63.2 Clinical features suggestive of severe pre-eclampsia

Blood pressure	Systolic arterial pressure >160 mmHg (21.3 kPa) Diastolic arterial pressure >110 mmHg (14.6 kPa)
Renal	Proteinuria ≥2 g/24 h Oliguria <500 mL/24 h Serum creatinine >0.09 mmol/L
Hepatic	Epigastric or right-upper-quadrant pain Elevated bilirubin and/or transaminases
Neurological	Persistent headaches Visual disturbances, papilloedema, clonus Convulsions (eclampsia)
Haematological	Thrombocytopenia Deranged coagulation tests Haemolysis
Cardiac/ respiratory	Pulmonary oedema Cyanosis

Renal changes include reduced glomerular filtration rate due to reduced renal plasma flow and filtration coefficient. These features, together with proteinuria, are associated with the characteristic lesion of glomeruloendotheliosis. Hyperuricaemia is associated with increased prenatal risk, particularly if serum uric acid concentration rises rapidly.

Haemostatic abnormalities include thrombocytopenia, which may be associated with decreased platelet function. Associated coagulation abnormalities may occur but are unlikely unless the platelet count is $<100\,000\times10^9$/L.[23,24]

Hepatic complications include liver oedema, hepatocellular necrosis, periportal and subcapsular haemorrhage, hepatic infarcts and rupture. Patients with HELLP syndrome (see below) are particularly at risk.

The leading causes of maternal death in pre-eclampsia/eclampsia are intracranial haemorrhage, pulmonary oedema and hepatic complications. Fetal morbidity results from placental insufficiency, prematurity and abruptio placentae.

MANAGEMENT

The principles of management include:

- timely delivery of the placenta and fetus
- supportive care before delivery, and during the immediate postpartum period, focusing on:
  - control of blood pressure
  - prevention of seizures with magnesium sulphate
  - maintenance of placental perfusion
  - prevention of complications
  - monitoring of fetal well-being.

Table 63.3 Management in severe pre-eclampsia

General measures	Keep patient in lateral position Stress ulcer prophylaxis DVT prophylaxis
Maternal monitoring	Intra-arterial blood pressure monitoring in severe cases Sp_{O_2}, urine output, intake–output chart Consider central venous catheter or pulmonary artery catheter
Investigations	Complete blood count, renal function and electrolytes Urate Liver function test Clotting profile Blood group matching Urinalysis
Fetal monitoring	Continuous fetal heart monitoring Other options as assessed by obstetricians: ultrasound, amniotic fluid index (AFI), umbilical artery Doppler
Magnesium sulphate prophylaxis and treatment of eclampsia	Intravenous regimen: loading dose 4 g over 10–15 min Maintenance 1–2 g/h Intramuscular regimen: 4 g every 4 h
For recurrent eclampsia	A further i.v. loading dose of 2–4 g over 10 min May increase maintenance up to 2 g/h
Antihypertensive therapy	Acute treatment indicated if SBP > 160 mmHg (21.3 kPa) *or* DBP > 110 mmHg (14.6 kPa) Control of blood pressure should be gradual and sustained while preserving maternal organ perfusion and placental perfusion
Liaison with obstetricians regarding timing of delivery	Antenatal steroid if gestation <34 weeks

The management for severe pre-eclampsia is summarised in **Table 63.3**.

If complications are avoided, the disease normally resolves completely after delivery. Transfer of the mother to a tertiary centre before delivery should be considered if a level III neonatal unit is not available (see Ch. 1). Admission into an ICU before delivery may be appropriate in severe cases, or when the labour ward lacks the expertise or equipment for intensive monitoring. Because prematurity is a major cause of neonatal morbidity, expectant management of select patients with severe pre-eclampsia <34 weeks' gestation to prolong pregnancy may improve outcomes.[25] This requires collaboration with obstetricians and careful balancing of the maternal and perinatal risks. In all cases, the maternal benefit should always outweigh the benefit of the fetus. Consulting a neonatologist for prenatal counselling is preferable if time is available. After delivery, severe cases should preferably be managed in an ICU for 24–72 hours.

ANTIHYPERTENSIVE THERAPY

The aim of antihypertensive therapy is to prevent maternal complications (intracerebral haemorrhage, cardiac failure and abruptio placentae) while maintaining placental blood flow. It is important to appreciate that hypertension is a marker and not a causal factor in pre-eclampsia. Therefore, although controlling hypertension reduces the risk of complications, it does not ameliorate the underlying pathological process. Acute treatment is indicated when blood pressure is greater than 160 mmHg (21.3 kPa) systolic or 105–110 mmHg (14–14.6 kPa) diastolic. Reduction of systolic pressure is particularly important for the prevention of stroke.[26] Initially, systolic blood pressure should only be reduced by about 20–30 mmHg (2.66–4 kPa) and diastolic pressure by 10–15 mmHg (1.33–2 kPa) while monitoring the fetus. Concomitant plasma expansion reduces the risk of sudden hypotension when vasodilators are used. Recommended antihypertensive drugs for acute treatment are summarised in **Table 63.4**.[1,2,5,27] The most commonly used drugs are labetalol, hydralazine and nifedipine; insufficient data are available to show which of these is superior.[28,29]

OTHER AGENTS

These agents are not routinely used and indicated only when hypertension is refractory to conventional treatment. *Sodium nitroprusside* (initial dose 0.25 μg/kg per min, maximum dose 5 μg/kg per min) can be used to reduce blood pressure rapidly in a hypertensive emergency but care should be taken in patients with depleted

Table 63.4 Drug treatment of hypertension in severe pre-eclampsia

DRUG	DOSAGE GUIDE	MECHANISM OF ACTION	NOTES
Labetalol	Bolus 20–40 mg i.v. every 10–15 min to maximum dose of 300 mg Infusion 1–2 mg/min, reducing to 0.5 mg/min or less after blood pressure is controlled	Non-selective beta-adrenergic receptor block with $alpha_1$-blocking effect	Reduces blood pressure without decrease in uteroplacental flow[29] Crosses placenta, but neonatal hypoglycaemia and bradycardia are rarely seen Need fetal heart monitoring Should not be given to patients with asthma or myocardial dysfunction
Hydralazine	Bolus 5 mg i.v. followed with 5–10 mg every 20 min to maximum of 20 mg	Direct arteriolar vasodilator	Slow onset of action of 10–20 min but may cause sudden hypotension Consider concomitant fluid bolus (<250 mL) Adverse effects include headache, tachycardia, tremor, nausea, rarely neonatal thrombocytopenia
Nifedipine	Oral route is preferred, 10 mg, repeat after 30 min as required (sublingual route may cause sudden hypotension)	Calcium channel blocker	Cause uterine muscle relaxation that may increase risk of postpartum haemorrhage Potentiation of neuromuscular block in patient receiving magnesium sulphate

intravascular volume and duration should be limited to <4 hours to avoid fetal cyanide poisoning. *Nitroglycerin* infusion (initial dose 5 μg/min, maximum dose 100 μg/min) may be useful in cases complicated by pulmonary oedema.

Methyldopa has been used for mild cases, but its slow onset time makes it unsuitable for acute treatment. *Diazoxide, ketanserin, nimodipine* and *magnesium* are not recommended as first-line agents. *Beta blockers* other than labetalol may cause decreased uteroplacental perfusion, fetal bradycardia and decreased fetal tolerance to hypoxia. *Angiotensin-converting enzyme inhibitors* and *angiotensin antagonists* should not be used before delivery because of adverse fetal effects. *Diuretics* should generally be avoided because pre-eclamptic patients have reduced plasma volume.

ANTICONVULSANT THERAPY

Anticonvulsants are used to prevent recurrent convulsions in eclampsia or to prevent initial convulsions in pre-eclampsia. Magnesium sulphate should be used as first-line treatment for prophylaxis and treatment of eclamptic seizures, and for prophylaxis of seizures in severe pre-eclampsia. The Magpie trial conducted in 33 countries showed that women in the magnesium group had a 58% (95% CI 40–71%) lower risk of eclampsia and probably lower maternal mortality.[30] Magnesium was more cost-effective in developing countries where pre-eclampsia is a more significant problem.[31] However, the benefits of using magnesium in mild pre-eclampsia are uncertain, especially in developed countries. Adverse maternal events are increased, and there is no reduction in maternal or perinatal morbidity.[32]

The mechanism of action of magnesium for preventing eclamptic seizures is unknown. Although abnormal electroencephalograms are frequent in pre-eclampsia and eclampsia, they are not altered by magnesium sulphate. Part of magnesium's action may be reduction of cerebral vasospasm via antagonism of calcium at membrane channels or intracellular sites. However, the cerebral vasodilator nimodipine was ineffective for preventing seizures.[33] Magnesium amplifies release of prostacyclin by vascular endothelium, and this may inhibit platelet aggregation and vasoconstriction. Doppler ultrasonography suggests that magnesium vasodilates smaller-diameter intracranial blood vessels, and some of its effects may be from relieving cerebral ischaemia. Part of the anticonvulsant activity of magnesium may be mediated by blockade or suppression of *N*-methyl-D-aspartate (NMDA) receptors. Magnesium has tocolytic effects and mild general vasodilator and antihypertensive actions, and increases renal and uterine blood flow.

Guidelines for administration of magnesium sulphate are summarised in Table 63.3. The kidney rapidly excretes magnesium. The half-life in patients with normal renal function is 4 hours and 90% of the dose is excreted by 24 hours after the infusion.[34] When there is renal impairment or oliguria the dose should be reduced and serum concentration should be monitored. Suggested target serum concentration for severe pre-eclampsia is 2–3.5 mmol/L (4–7 mEq/L or 4.8–8.4 mg/dL). Magnesium toxicity is associated with muscle weakness and may lead to respiratory paralysis (>7.5 mmol/L). Increased conduction time with increased PR and QT intervals and QRS duration can lead to sinoatrial and atrioventricular block

(>7.5 mmol/L) and cardiac arrest in diastole (>12.5 mmol/L). Toxicity is unlikely when deep tendon reflexes are present (the upper limb should be used during epidural analgesia). Magnesium toxicity can be treated with small intravenous doses of calcium and enhanced clearance with renal replacement therapy when it is associated with renal failure. Other reported adverse effects of magnesium include death from overdose, increased bleeding, slowed cervical dilatation and increased risk of pulmonary oedema. Magnesium crosses the placenta and can cause neonatal flaccidity and respiratory depression.

ECLAMPSIA

With modern obstetric care, eclampsia may present without marked preceding hypertension or proteinuria, and up to 40% of cases occur postpartum, often more than 48 hours after delivery.[35,36] Priorities in the management of eclamptic seizures are airway protection, oxygenation, and termination and prevention of seizures. Delivery of the fetus should be considered after maternal stabilisation. Patients should be placed in the left-lateral position and given oxygen. Magnesium should be given if not already started. A further 2 g loading dose of $MgSO_4$ can be given if the patient is already on magnesium therapy (see Table 63.3). Approximately 10% of eclamptic patients will have a recurrent seizure despite receiving magnesium. Prolonged seizures can be terminated by diazepam 5–10 mg intravenously. If seizures are refractory, thiopental and suxamethonium should be given and the airway secured.

It is important to appreciate that eclampsia is not the only cause of seizure during pregnancy. Recurrent convulsions or prolonged unconsciousness may indicate additional cerebral pathology (e.g. cerebral oedema, intracerebral haemorrhage, venous thrombosis) and an urgent computed tomographic (CT) scan should be done whenever possible.

OTHER ANTICONVULSANTS

If repeated seizures occur despite therapeutic levels of magnesium, conventional anticonvulsants can be considered, but it is important to exclude other causes of convulsions. Although diazepam and phenytoin are inferior to magnesium for preventing eclamptic seizures, these agents may be considered when magnesium sulphate is contraindicated (e.g. renal failure, muscle weakness, allergy).

Diazepam as a bolus dose could be considered for immediate treatment of convulsions while preparing for magnesium therapy. Intravenous infusion of diazepam has been used (40 mg diazepam in 500 mL normal saline titrated to keep patients sedated but rousable) as prophylaxis when magnesium therapy is contraindicated.

Phenytoin is given as an initial intravenous loading dose of 10 mg/kg followed 2 hours later by 5 mg/kg. Doses are diluted in normal saline and given no faster than 50 mg/min. Electrocardiogram and arterial pressure should be monitored. Maintenance doses of 200 mg orally or intravenously are started 12 hours after the second bolus and given 8-hourly. However, there is no consensus on the optimal dosing regimen. Monitoring of phenytoin level is necessary to avoid toxicity.

FLUID BALANCE

Fluid management in pre-eclampsia is controversial. Pre-eclamptic patients usually have reduced circulating intravascular volume. There may also be a significant decrease in blood pressure upon initiation of antihypertensive therapy, particularly with hydralazine. However, the effectiveness of fluid loading is uncertain,[37] and there is a risk of pulmonary oedema. Oliguria is common in patients with pre-eclampsia, but this does not necessarily imply volume depletion. Hence fluid challenge should be considered for treatment of oliguria only when there are other signs of hypovolaemia. Renal failure in pre-eclampsia is uncommon. Some patients with persistent oliguria and a rising serum creatinine concentration may require a period of continuous renal replacement therapy, but the majority of cases recover. However, the risk of irreversible renal damage is greater when there is associated abruptio placentae, disseminated intravascular coagulation (DIC), hypotensive shock, or sepsis.

Low-dose dopamine (3 µg/kg per min) infusions have been used after correction of hypovolaemia to improve urine output, but they have not been shown to improve renal outcome and are no longer recommended.[38]

Furosemide could be considered if pulmonary oedema develops. Furosemide should not be used to treat oliguria without pulmonary oedema because this may exacerbate the fluid-depleted state.

There is controversy over the effectiveness of CVP and pulmonary capillary wedge pressure (PCWP) for assisting fluid management in pre-eclamptic patients. CVP and PCWP have poor correlation, especially when CVP is greater than 6 mmHg (0.8 kPa).[39] Optimal CVP and PCWP values are unknown, but the measured response to fluid challenge may be informative and useful. Pulmonary artery catheterisation placement carries inherent risks and should be considered only when there are clear indications (e.g. refractory hypertension, pulmonary oedema, severe cardiac disease and refractory oliguria), and the obtained data will be used to guide decision making.[39] Should pulmonary oedema develop, it is managed with oxygen therapy, positive end-expiratory pressure with or without ventilation, inotropes, vasodilators, morphine or diuretics as indicated. The echocardiogram can be used for

assessment of cardiac function and guiding further therapy.[40]

POSTPARTUM CARE

Patients are frequently referred to an ICU for postpartum care, particularly after caesarean delivery. Pre-eclampsia may persist or even develop post partum.[41] The risk of pulmonary oedema is greatest after delivery. After delivery, there is often an initial improvement with a relapse in the first 24 hours. Magnesium should be continued for 24 hours after delivery or the last seizure. Ongoing monitoring for signs of severe pre-eclampsia should be continued in the postpartum period. Antihypertensive drugs may be reduced according to the blood pressure. Some patients may require a change to oral medication that may need to be continued for several weeks. Psychological support is important, especially if there has been an adverse neonatal outcome. Full recovery from the organ dysfunction of pre-eclampsia is normally expected within 6 weeks. However, patients are more likely to develop pre-eclampsia in subsequent pregnancies, and have double the risk of early cardiovascular disease and mortality.[42]

HELLP SYNDROME AND HEPATIC COMPLICATIONS

HELLP syndrome is a particularly high-risk form of pre-eclampsia characterised by more pronounced hepatic rather than cerebral or renal involvement. Diagnosis is based on laboratory findings showing *h*aemolysis (microangiopathic haemolytic anaemia), *e*levated *l*iver enzymes and *l*ow *p*latelets, although exact criteria vary.[43,44] The pathogenesis of HELPP is similar to that of early-onset pre-eclampsia, but biomarker derangements are more severe.[45] Clinical presentation is variable. Many patients have non-specific signs such as right-upper-quadrant or epigastric pain, nausea, malaise or headache. Although most patients will have hypertension and proteinuria, these can be mild or absent. Important differential diagnoses include idiopathic thrombocytopenic purpura, systemic lupus erythematosus, thrombotic thrombocytopenic purpura, haemolytic–uraemic syndrome and acute fatty liver of pregnancy. Typically, HELLP syndrome presents at early gestational ages and is more common in white and multiparous women. In about 30% of cases, it first presents in the postpartum period, sometimes with no evidence of pre-eclampsia before delivery. After delivery, patients usually show a continuing deterioration in platelet count and liver enzymes, with a peak in severity 24–48 hours after delivery followed by gradual resolution and complete recovery if complications are avoided. Complications of HELLP syndrome include DIC, abruptio placentae, acute renal failure, pulmonary oedema, severe ascites, pleural effusion, liver haemorrhage or failure, acute respiratory distress syndrome (ARDS), sepsis and stroke.

Patients with HELLP should be managed aggressively, similarly to pre-eclampsia, with an emphasis on stabilisation and delivery.[46] Expectant management of patients with gestation less than 34 weeks has been described but the relative benefits and risks of this are controversial.[44]

Corticosteroids are given to promote fetal lung maturation before premature delivery, but there is controversy concerning the use of high-dose corticosteroids for maternal benefit. The anti-inflammatory actions of corticosteroids are postulated to be beneficial for the disease, and the platelet count is increased. Although corticosteroids are part of a standardised protocol at one hospital,[47] a recent Cochrane review of 11 trials concluded that there is no difference in maternal or perinatal death, and no evidence of significant maternal benefit.[48] Plasma exchange with fresh frozen plasma has been described for postpartum patients with delayed resolution of HELLP, with variable response.[49]

Life-threatening hepatic complications may occur in pre-eclampsia, particularly in patients with HELLP syndrome. These include segmental hepatic infarction, parenchymal haemorrhage and subcapsular haemotoma with or without rupture. If suspected, patients should have an urgent CT scan. Hepatic rupture is a surgical emergency. Hepatic haemorrhage without rupture has been managed conservatively.

ANAESTHESIA AND ANALGESIA

Platelet count and coagulation tests should be checked before regional anaesthesia. Epidural analgesia in labour reduces fluctuations in arterial pressure and improves placental blood flow.[50] For caesarean delivery, the use of epidural or spinal anaesthesia avoids the risks of aspiration, difficult intubation from airway oedema, exaggerated hypertensive response to intubation and magnesium-induced sensitivity to muscle relaxants associated with general anaesthesia.

If general anaesthesia is required, smaller-size endotracheal tubes may be required. The hypertensive response to intubation should be attenuated with drugs such as fentanyl (2.5 μg/kg), alfentanil (10 μg/kg), magnesium sulphate (40 mg/kg), a combination of alfentanil (7.5 μg/kg) with magnesium sulphate (30 mg/kg), or remifentanil (1 μg/kg). Occasionally, awake intubation under topical anaesthesia may be necessary when there is airway obstruction.

General obstetric emergencies

Winnie TP Wan and Tony Gin

The intensive care unit (ICU) will receive obstetric patients with the usual range of medical and surgical emergencies, and also provide supportive care for patients who suffer specific obstetric complications. The pattern of admission varies widely among countries with different standards of obstetric care. A recent prospective cohort study in the Netherlands reported the incidence of ICU admission to be 2.4 per 1000 deliveries. The most common reasons for ICU admission were major obstetric haemorrhage, hypertensive disorder of pregnancy and sepsis.[1] Data from the Centre for Maternal and Child Enquiries (CMACE) in the United Kingdom showed that the overall maternal mortality rate for the triennium 2006–2008 was 11.39 per 100 000 maternities, with the commonest cause of direct death now being sepsis (1.13 per 100 000 maternities).[2] Over half of the mothers that die will spend some time in an ICU, and many die there. This latest report highlighted the need for early consultation by obstetricians to intensivists, and discussed in more detail the management of sepsis and haemorrhage.

PATHOPHYSIOLOGY

Two important points to recognise in treating obstetric patients are:

1. During pregnancy, the normal ranges for physiological variables change (**Table 64.1**).[3] This may modify the presentation of the problem, variables used to guide treatment, and the response to treatment. The majority of physiological changes revert to normal several days after delivery.
2. Both mother and fetus are affected by the pathology and subsequent treatment.

AIRWAY AND VENTILATION

Several factors may complicate tracheal intubation in pregnancy:

- altered anatomy in pregnancy predisposes to a potentially difficult airway
- oedematous tissues
- delayed gastric emptying
- increased oxygen consumption.

Intensivists must be familiar with the difficult airway algorithm and the use of the laryngeal mask airway.[4,5] Avoidance of intubation and the use of non-invasive ventilation may, in selected cases, be a good option.

CIRCULATION

Tachycardia, low blood pressure, increased cardiac output and warm peripheries are normal in late pregnancy. After 20 weeks' gestation, aortocaval compression by the gravid uterus can decrease uterine perfusion and venous return to the heart. This is best prevented by using the full left-lateral position, but a left-lateral tilt or manual displacement of the uterus may be more practicable.

Haemodynamic support should generally start with good hydration, and assessment should take into account the altered cardiovascular variables in pregnancy. Non-invasive cardiac output monitoring is inaccurate and invasive monitoring with pulmonary artery catheters may be helpful in severe pre-eclampsia, pulmonary oedema and cardiac disease.[6] The uterine vascular bed is considered maximally dilated but still responsive to stimuli that cause vasoconstriction, such as circulating catecholamines. Ephedrine has traditionally been the vasoconstrictor used in obstetrics because it was thought to preserve uterine blood flow better than pure alpha agonists. However, alpha agonists such as phenylephrine are more effective and not associated with fetal acidosis when used to manage hypotension during caesarean delivery.[7] There is no evidence favouring any particular inotrope.

COAGULATION

Pregnancy is associated with a fivefold increase in thromboembolism, and patients should be given thromboembolic prophylaxis, typically with unfractionated heparin or low-molecular-weight heparin (LMWH) and elastic compression stockings.

MOTHER AND FETUS

In the critically ill it is important to monitor the fetus because of the problems associated with:

Table 64.1 Changes in physiological variables during pregnancy

PARAMETER	NON-PREGNANT	FIRST TRIMESTER	SECOND TRIMESTER	THIRD TRIMESTER
CARDIOVASCULAR				
SBP (mmHg)	110 (14.63 kPa)		100 (–8%)	105 (–5)
MAP (mmHg)	90 (11.97 kPa)			85 (–5)
DAP (mmHg)	60 (7.98 kPa)		50 (–12%)	50 (–12)
CVP (mmHg)	4 (0.53 kPa)			4 (no change)
PCWP (mmHg)	6 (0.8 kPa)			6 (no change)
HR (b.p.m.)	75	82 (+10%)	82 (+10%)	90 (+25%)
SV (mL)	65	80 (+20%)	85 (+30%)	82 (25%)
CO (L)	5	6.5 (+30%)	7 (+50%)	7 (+50%)
SVR (dyn cm/s^{-5})	1530			1210 (–20%)
PVR (dyn cm/s^{-5})	119			78 (–30%)
Total blood vol (L)	3.2	3.5 (+10%)	4.1 (+30%)	4.6 (+45%)
Haematocrit				–33%
Plasma albumin (g/L)	35			30
Oncotic pressure (mmHg)	28 (3.72 kPa)			25 (–3–0.4 kPa)
RESPIRATORY				
pH	7.40	7.44	7.44	7.44
Pa_{CO_2} (mmHg)	40 (5.32 kPa)	30	30	30
Pa_{O_2} (mmHg)	100 (13.3 kPa)	107	105	103
HCO_3 (mmol/L)	24	21	20	20
TV (mL)	500			700 (+40%)
RR (breath/min)	15			17 (+15%)
MV (mL/min)	7500			10 500 (+40%)
FRC (mL)	2800			2300 (–20%)
VC (mL)	3500			3500 (no change)
IC (mL)	2200			2500 (+15%)
ERV (mL)	1300			1100 (–20%)
RV (mL)	1500			1200 (–20%)
TLC (mL)	5000			4800 (–5%)
O2 consumption (mL/min)	250			300 (+20%)

SBP=systolic arterial pressure; MAP=mean arterial pressure; DBP=diastolic arterial pressure; CVP=central venous pressure; PCWP=pulmonary capillary wedge pressure; HR=heart rate; SV=stroke volume; CO=cardiac output; SVR=systemic vascular resistance; PVR=pulmonary vascular resistance; TV=tidal volume; RR=respiratory rate; MV=minute volume; FRC=functional residual capacity; VC=vital capacity; IC=inspiratory capacity; ERV=expiratory reserve volume; RV=residual volume; TLC=total lung capacity.

- premature labour
- the placental transfer of drugs
- maintenance of placental perfusion and oxygenation.

An obstetric opinion should be sought as soon as possible regarding cardiotocography, ultrasound examination and timing of delivery. Nutrition is also very important for the fetus and adequate maternal feeding should be started as soon as possible. Neither perineal nor breast nursing care should be neglected.

CARDIOPULMONARY RESUSCITATION

Despite being younger than the more usual cardiac arrest patients, pregnant patients have a poor survival rate.[10,11] The obstetrician and neonatologist should be

notified when the cardiac arrest call is activated, and preparations be made for perimortem caesarean delivery.

MODIFICATION OF CPR

The 2010 International Liaison Committee on Resuscitation (ILCOR) guideline emphasises the importance of good-quality chest compression, and suggests rescuers may consider starting CPR with chest compression rather than ventilations (the sequence changes from 'ABC' to 'CAB').

After about 20 weeks' gestation, the gravid uterus can compress the inferior vena cava and impede venous return and cardiac output from CPR. Positioning for obstetric CPR should aim at relieving aortocaval compression and optimising the quality of chest compression. It can be done by manual left uterine displacement in the supine position first, either at the patient's left side with a two-handed technique, or at the patient's right side with a one-handed technique. The mother can also be placed in left-lateral tilt of 27–30° using a firm wedge to support the pelvis and thorax. Chest compression should be performed with a slightly higher hand position (slightly above the centre of the sternum). Airway management in pregnant patients is generally more difficult. Bag-mask ventilation with high-flow oxygen before intubation is especially important. Early tracheal intubation after cricoid pressure will facilitate ventilation and decrease the risk of acid aspiration. During advanced life support (ALS), drugs are given and defibrillation performed according to the normal protocols. Apical placement of the paddle may be difficult because of position and breast enlargement, and adhesive defibrillation pads are preferred. Fetal or uterine monitors should be removed before defibrillation.

Case reports at advanced gestation indicate that both maternal and fetal survival from cardiac arrest may depend on prompt caesarean delivery to relieve the effects of aortocaval compression. The ILCOR advisory statement suggests that the resuscitation team leaders should activate the protocol for an emergency caesarean delivery as soon as cardiac arrest is identified in a pregnant woman with an obviously gravid uterus. Emergency caesarean section may be considered at 4 minutes after onset of maternal cardiac arrest if there is no return of spontaneous circulation.

POST-RESUSCITATION CARE

Therapeutic hypothermia has been shown to improve outcome in post-arrest adult patients. There is one case report of hypothermia in early pregnancy without emergency caesarean section, but not in patients after perimortem caesarean section. The ILCOR 2010 guideline suggests hypothermia may be considered on an individual basis in comatose pregnant patients.

TRAUMA

More than 10% of pregnancy-related traumas are associated with the use of illicit drugs or alcohol. Most injuries occur as the result of motor vehicle accidents, and other common causes are suicide (usually postpartum), falls and assaults.

Special considerations of trauma in obstetric patients include the potential for miscarriage, preterm rupture of membrane, placenta abruptio, inadequate uteroplacental blood flow, preterm labour, and fetal distress and demise. The gravid uterus displaces the bowel cephalad so visceral injuries are less common after lower abdominal injuries. The dilated pelvic vasculature increases the risk of retroperitoneal hemorrhage following pelvic injuries. Head injuries and haemorrhagic shock account for most maternal deaths, whereas placental abruption and maternal death are the most frequent causes of fetal death.[14]

PRIMARY AND SECONDARY SURVEY

Initial resuscitation should follow the normal plan of attention to airway, breathing and circulation.[15] Unless a spinal injury is suspected, the pregnant patient should be transported and examined in the left-lateral tilt position or with manual left uterine displacement. Blood volume is increased during pregnancy and hypotension may not be evident until 35% or more of total blood volume is lost. Uterine blood flow is not autoregulated and may be decreased despite normal maternal haemodynamics, so that slight overhydration may be preferred to underhydration. Excessive resuscitation with crystalloids or non-blood colloids may increase the mortality from severe haemorrhage. Drug treatment of modest hypotension can be started with ephedrine, but more potent vasopressors should be used if necessary. Continuous fetal heart rate monitoring should be used.

In trauma assessment the increased significance of pelvic fractures in terms of uterine injury and retroperitoneal haemorrhage should be considered.

- Ultrasound is the investigation of choice.
- Diagnostic peritoneal lavage, if performed, should be through an open surgical incision above the fundus.
- Chest drains are placed slightly higher than normal, in the third or fourth intercostal space.
- It is important to exclude herniation of abdominal contents through a ruptured diaphragm.
- Vaginal examination to look for either leak of amniotic fluid and/or vaginal bleeding is vital.

Necessary radiological investigations should be performed as indicated as the radiation hazard to the fetus is very small, except in the early first trimester when exposure to more than 50–100 mGy is a cause for concern. A chest X-ray delivers less than 5 mGy to the lungs and very little to the shielded abdomen. The fetal

radiation dose from abdominal examinations can range from 1 mGy for a plain film up to 20–50 mGy for an abdominal pelvic computed tomography (CT) with fluoroscopy.[16]

DEFINITIVE CARE

Cardiotocographic monitoring is considered essential, but there is wide variation in practice and recommended duration of monitoring. Premature labour and placental abruption may not be diagnosed unless regular monitoring is continued for at least 6 hours and even 24 hours if indicated.[17] Rh immune globulin 300 μg should be considered for all Rh D-negative within 72 hours of injury to prevent future Rh alloimmunisation of the newborn. The Kleihauer–Betke test can be used to detect fetal blood in the maternal circulation and give an estimate of the volume of feto-maternal haemorrhage.

BURNS

Approximately 7% of women of reproductive age are seen for treatment for major burns.[18] Although the women are usually young and healthy, pregnancy is already a hypermetabolic state and the fetus is at great risk from many complications.[19] Factors influencing morbidity and mortality include the depth and size of burn wound, the underlying health and age of the pregnant women, the estimated gestational age of the fetus, associated inhalational injury, and significant secondary complications. Preterm labour and stillbirth are more likely in the first few days after the burn injury. The presumed pathogenesis is due to the high levels of prostaglandins and maternal acidosis.[20]

SPECIAL CONSIDERATIONS IN PREGNANT BURN PATIENTS[20]

FLUID RESUSCITATION

Replacement of fluid loss from burns must keep in mind the normally increased circulating volume of pregnancy. Pregnant burn patients usually require significantly more fluid to maintain haemodynamic stability. Pregnancy affects the total body surface area (TBSA) as the abdomen increases in size. The Lund–Browder chart is still the commonly used method for burn area estimation.

DEFINITIVE BURN CARE

Continuous enteral feeding should be initiated as soon as possible and can be within the first 24 hours of burn. Canadian Clinical Practice Guidelines suggest enteral glutamine should be considered in burn patients, but its role in pregnant burn patients is unclear.[21] Topical povidone-iodine solution should be avoided because the iodine may be absorbed and affect fetal thyroid function. Inhalational injuries with hypoxia and carbon monoxide are especially detrimental to the fetus, because carbon monoxide has a greater affinity and longer half-life when it is bound to fetal haemoglobulin.

SEVERE OBSTETRIC HAEMORRHAGE

Obstetric haemorrhage accounts for 25–30% of all maternal mortality.[22] The aim of management is rapid restoration of circulating volume, correct coagulopathy and remedy the underlying cause of haemorrhage.

Antepartum haemorrhage is defined as bleeding from the genital tract after 24 weeks of gestation. Its incidence is 2–5% of all pregnancies.[23] The common causes are placenta praevia and placental abruption; both are ultimately managed by delivery. In placenta praevia, the placenta implants in advance of the presenting part and classically presents as painless bleeding during the second or third trimester. Placenta praevia is relatively common (1 in 200 pregnancies) but severe haemorrhage is relatively rare. In placental abruption, a normally implanted placenta separates from the uterine wall. The incidence of placental abruption is low (0.5–2%) but perinatal mortality may be as high as 50%. In concealed abruption, vaginal bleeding can be absent and several litres of blood may be concealed in the uterus.

Postpartum haemorrhage is most commonly due to uterine atony and abnormal placentation, with retained tissues, trauma to the genital tract and coagulopathy as other causes. In an emergency, the aorta can be compressed against the vertebral column by a fist pressed on the abdomen above the umbilicus.

Uterine atony is managed initially with bimanual compression, uterine massage and drugs that include:[24]

- *oxytocin:* 5 units slow intravenous injection, or infusion (40 units in 500 mL Ringer's lactate solution at 125 mL/h)
- *ergonovine (ergometrine):* 0.5 mg slow intravenous or intramuscular injection (contraindicated in patients with hypertension)
- *carboprost:* 250 μg intramuscular injection, repeated at intervals of not less than 15 minutes to a maximum of 8 doses (contraindicated in patients with asthma) or 500 μg direct intramyometrial injection
- *misoprostol:* 1000 μg rectally.

If bleeding persists, tamponade techniques using gauze packs or balloons can be useful. Otherwise, specific invasive management such as angiographic arterial embolisation, laparotomy for uterine haemostatic suturing techniques such as B-lynch and multiple square sutures, surgical bilateral uterine artery ligation, or definitive hysterectomy may be required. Recombinant factor VIIa has also been used; the recommended initial dose is 90 μg/kg, and a second dose

can be given 20–60 minutes after the first dose if there is no response.

For patients with known and suspected risk factors for postpartum haemorrhage, prophylactic interventional radiology can be employed. Balloons are placed in the internal iliac or uterine arteries before delivery. The balloons then can be inflated to occlude the vessels in the event of postpartum haemorrhage.[25]

With massive bleeding and transfusion, there should be no need to wait for a coagulation profile before giving coagulation factors. Disseminated intravascular coagulation still develops in 10–30% of cases, partly because tissue thromboplastin is released during abruption.

SEPSIS AND SEPTIC SHOCK

Maternal sepsis and septic shock are relatively uncommon. However, sepsis should always be carefully considered because the underlying physiological changes in pregnancy and the response to labour can confound the presentation of sepsis and make its diagnosis difficult. The most common sources of infection are chorioamnionitis, postpartum endometritis, urinary tract infections, pyelonephritis and septic abortion. Animal studies suggest that pregnancy increases the susceptibility to endotoxin, and that metabolic acidosis and cardiovascular collapse occur earlier.

Management of septic shock follows the same guidelines as for non-pregnant population, with initial resuscitation, source control and prompt antibiotics. Gram-negative organisms are the frequent causative organisms, but streptococci and *Bacteroides* may also be present. Antimicrobial therapy is dependent on hospital prevalence and susceptibility patterns; empirical broad-spectrum therapy should be started early. Typical combinations are ampicillin, gentamicin and clindamycin, or carbapenem and vancomycin. Tetracyclines and quinolones should not be used in pregnancy.

Other treatment modalities, including insulin therapy, corticosteroids and activated protein C were never evaluated in pregnancy.

VENOUS THROMBOEMBOLISM

The incidence of venous thromboembolism (VTE) ranges from 0.6 to 1.3 episodes per 1000 deliveries, which is a fivefold to tenfold increase in risk compared with those reported in non-pregnant women of comparable age. Pulmonary thromboembolism is a common cause of maternal death, accounting for 15–25% of maternal mortality. Pregnancy is associated with increased risk of VTE because of:

- venous stasis
- hypercoagulable state
- vascular injury associated with delivery.

Accurate diagnosis of venous thromboembolism is crucial because of the long-term implications for therapy. Symptoms of dyspnoea or pain in the leg or chest require accurate diagnosis, especially in the immediate postpartum period. Although contrast venography is the gold-standard test for diagnosing deep-vein thrombosis, the radiation exposure and invasive nature of the test mean that duplex Doppler ultrasonography is the usual first choice. D-dimer testing may also be useful but a positive test must be interpreted carefully because D-dimer values normally increase throughout pregnancy. Venography, perfusion lung scanning, pulmonary angiography and helical CT scan should not be avoided if indicated.

TREATMENT OF VTE DURING PREGNANCY[28]

Treatment is either subcutaneous LMWH or intravenous unfractionated heparin. LMWH has gradually replaced unfractionated heparin, based on the results of large trials in non-pregnant patients showing that LMWHs are at least as safe and effective as unfractionated heparin. In addition, the risk of heparin-induced thrombocytopenia and osteoporosis appears lower with LMWH than unfractionated heparin. The need for dose adjustments in proportion to change in weight over the course of pregnancy remains controversial. Full-dose anticoagulation should be continued during pregnancy. Subcutaneous LMWH can be discontinued 24–36 hours, and intravenous unfractionated heparin 4–6 hours, before elective induction of labour or caesarean section. A temporary retrievable venous filter can be inserted and removed postpartum. LMWH or unfractionated heparin should be restarted in the postpartum patient for at least 6–12 weeks. Neuraxial anaesthesia should not be used on patients with full anticoagulation.

With life-threatening massive pulmonary embolus, surgical treatment or thrombolysis must be considered. Thrombolysis was thought to be relatively contraindicated during pregnancy because of the risk of maternal and fetal haemorrhagic complications. No controlled trials are feasible and outcome data must be extracted from case reports. A review found that thrombolytic therapy was associated with a low maternal mortality rate of 1%, with a 6% rate of fetal loss and 6% rate of premature delivery.[29] The fetal risks appear to be lower than that obtained with surgical intervention in pregnant patients, and maternal risks lower than reported risks for surgery, thrombolysis or transvenous filters in non-pregnant patients. Although heparin remains the treatment of choice, thrombolysis appears to be a viable option except during the immediate postpartum period.

AMNIOTIC FLUID EMBOLISM (AFE)

The incidence of AFE has been reported as 1 in 13 000 deliveries in the United States, and 1 in 50 000 deliveries

in the UK.[31,32] The maternal mortality rate in developed countries ranges from 13% to 61%.

PATHOPHYSIOLOGY

The pathophysiology of AFE remains uncertain. Traditionally, it is thought that amniotic fluid and fetal debris enter the maternal circulation by forceful uterine contraction. However, recent studies show that fetal cells are commonly found in the maternal circulation. AFE has more in common with anaphylaxis and septic shock than other embolic diseases. The exact trigger is unknown. There is an abnormal maternal immune response to fetal antigen exposure, and inflammatory mediators cause pulmonary vasoconstriction, complement activation and coagulopathy. Recently, the term 'anaphylactoid syndrome of pregnancy' has been proposed.

CLINICAL PRESENTATION

AFE is a clinical diagnosis. Classically, patients present with severe dyspnoea, cyanosis, sudden cardiovascular collapse, and coma or convulsions during labour, but AFE may occur earlier during pregnancy, during delivery or in the early puerperium. Some patients may present with bleeding and most patients eventually develop a coagulopathy.

Animal studies indicate that AFE causes a biphasic haemodynamic response. The early phase probably lasts less than half an hour and is characterised by severe hypoxia and right heart failure as a result of pulmonary hypertension from vasoconstriction or vessel damage. Patients who survive this first phase develop left ventricular failure with return of normal right ventricular function. Left ventricular failure may be a result of the initial hypoxia or the depressant effects of mediators. Disseminated intravascular coagulation is present in most patients. It could be caused by a specific activator of factor X, tissue factor or other substances, such as trophoblasts, in the amniotic fluid.

TREATMENT

Treatment is supportive. Assessment of central venous pressure may be misleading, and early pulmonary artery catheterisation has been advocated in a series reporting 100% survival in 5 patients by treating left ventricular failure aggressively.[33] The differential diagnoses must be evaluated quickly. Survivors of AFE regain normal cardiorespiratory function but may have neurological sequelae.

ACUTE RESPIRATORY FAILURE

Pregnant women should receive medication for optimal asthma control. There is no evidence that appropriate use of inhaled glucocorticosteroids, beta agonists and leukotriene modifiers is associated with increased incidence of fetal abnormalities. In contrast, there is a substantial risk of preterm delivery posed by poorly controlled maternal asthma.[34] Acute exacerbation should also be treated aggressively with systemic glucocorticosteroids when necessary.

Pulmonary oedema is more likely in the pregnant patient (1:1000 pregnancies) because of the increased cardiac output and blood volume, and the decreased plasma oncotic pressure. The principles of treatment are relatively straightforward in terms of determining the cause of the oedema and improving oxygenation, although it can be difficult to distinguish between hydrostatic and permeability oedema.

The prevalence of acute respiratory distress syndrome during pregnancy has been estimated at 16–70 cases per 100 000 pregnancies, with mortality rates from 23 to 50%.[35] Important causes of ARDS in pregnancy are sepsis, aspiration and pre-eclampsia. Non-invasive positive pressure ventilation has not been evaluated for treatment of hypoxaemic respiratory failure in pregnancy. Clinical criteria for intubation are similar to those in non-pregnant patients, but arterial blood gases must be interpreted carefully because of the underlying respiratory alkalosis in pregnancy. The ARDS Network lung protective strategy can be adopted in pregnant patients by using the non-pregnant predicted body weight and gestational age-appropriate blood gas targets. Permissive hypercapnia may cause fetal respiratory acidosis that will reduce the ability of fetal haemoglobin to bind oxygen. Furthermore, transfer of CO_2 across the placenta requires a gradient of 10 mmHg (1.33 kPa). Therefore, $Pa\text{CO}_2$ should probably be kept below 45 mmHg (6.0 kPa) and $Pa\text{O}_2$ above 70 mmHg (9.3 kPa). If conventional ventilation fails, the effectiveness of alternative strategies is unknown.[35] There are case reports of the use of extracorporeal membrane oxygenation (ECMO) in pregnant patients with severe ARDS.[36]

ACID ASPIRATION (MENDELSON'S SYNDROME)

Obstetric patients are at increased risk of acid aspiration because of decreased gastric emptying, increased gastric acidity and volume and increased intra-abdominal pressure. Aspiration of acidic material will cause acute lung injury, the severity being related to the amount, content and acidity of the aspirate.

The initial presentation is hypoxaemia and bronchospasm. Chemical pneumonitis and increased permeability pulmonary oedema develop over several hours.

Treatment includes standard respiratory support. Rigid bronchoscopy may be required to remove large food particles. Bronchoalveolar lavage and steroids are not useful and antibiotics should only be given for proven infection.

PERIPARTUM CARDIOMYOPATHY (PPCM)

Peripartum cardiomyopathy is characterised by new onset of heart failure between 1 month before and 5 months after delivery in previously healthy women. Diagnosis requires echocardiographic evidence of left ventricular dysfunction (ejection fraction <45%). The incidence varies from 1:100 to 1:10000 pregnancies. PPCM often presents as acute heart failure. The echocardiogram usually shows features of dilated cardiomyopathy.

The exact aetiology of PPCM remains controversial. A number of mechanisms have been proposed, including genetic factors, volume overload, viral illness, autoimmune, and hormonal imbalance. Treatment is largely supportive with diuretics, inotropes and non-invasive positive-pressure ventilation (NIPPV). Intra-aortic balloon pump and left ventricular assist device may be used in severe case. Recently, 16 kDa prolactin has been shown to have detrimental effects on the maternal heart. A small-scale randomised study showed that addition of bromocriptine to standard heart failure therapy can improve left ventricular ejection fraction.[38]

TOCOLYTIC THERAPY AND PULMONARY OEDEMA

Pulmonary oedema is an uncommon (1 in 400 pregnancies) but serious complication of tocolytic therapy with beta-adrenergic agonists. The underlying mechanism for pulmonary oedema is unclear, but it is probably related to fluid overload and the cardiovascular effects of beta-adrenergic agonists leading to increased pulmonary capillary hydrostatic pressure. The initial management of pulmonary oedema is discontinuation of the beta-adrenergic agonist and oxygen therapy, with further monitoring, diuretics and respiratory support as necessary. This problem should disappear as alternative tocolytics such as nifedipine and atosiban are used.

COCAINE TOXICITY

Cocaine abuse during pregnancy has become a significant problem in the USA, affecting more than 30 million people, with 90% of the women of child-bearing age. Cocaine has local anaesthetic and sympathomimetic actions and can cause:

- hypertension, dysrhythmias, myocardial ischaemia and infarction
- tachycardia and increased cardiac output, but decreased uterine blood flow
- increased uterine contractility.

Patients commonly present with chest pain, cardiovascular complications, or placental abruption and fetal distress. Acute toxicity may also mimic pre-eclampsia by presenting with cerebral haemorrhage or convulsions.

For the treatment of hypertension, the drug of choice is controversial. Although hydralazine is often used in obstetrics to treat maternal hypertension, labetalol is also widely used. However, concerns about beta blockers allowing unopposed alpha-adrenergic stimulation may also apply to a lesser extent with labetalol, and calcium channel antagonists and nitroglycerin have also been advocated. Nitroglycerin and benzodiazepines have been recommended for the treatment of cocaine-related myocardial ischaemia and infarction.

OVARIAN HYPERSTIMULATION SYNDROME

Ovarian hyperstimulation syndrome (OHSS) is a rare iatrogenic complication of ovarian stimulation usually occurring during the luteal phase or early part of pregnancy. The prevalence of severe OHSS is low, at 0.5–5% of stimulated ovarian cycles. However, it is becoming more recognised owing to the increasing number of women undergoing assisted reproductive technique.

The exact aetiology and pathogenesis of OHSS remain uncertain. It appears that exogenous or endogenous human chorionic gonadotropin (hCG) is the central triggering factor. OHSS usually occurs a few days after follicular rupture or follicular aspiration, after follicular growth has been medically stimulated or induced with either gonadotropins or clomiphene citrate. The stimulated ovaries become markedly enlarged with overproduction of ovarian hormones and vasoactive substances, including cytokines, angiotensin and vascular endothelial growth factor (VEGF). As a result, the capillary permeability increases leading to hypovolaemia with haemoconcentration, oedema and accumulation of fluid in the abdomen and pleural spaces.

OHSS can be classified as mild, moderate, severe or life threatening. For the life-threatening form, patients could have oliguria, renal failure, tense ascites, hydrothorax, thromboembolism, pericardial effusion, liver derangement, ovarian torsion, cerebral oedema and ARDS.

The treatment of OHSS is supportive until the condition resolves. In most cases, the syndrome follows a self-limiting course that parallels the decline in serum hCG level. Invasive haemodynamic monitoring is necessary to assist fluid management. Abdominal and pleural tapping is needed to release the accumulated fluid. Albumin can be used as a plasma expander. Prophylaxis for thromboembolism with anticoagulant should be given, and surgical intervention may be necessary for ovarian torsion.

Severe pre-existing disease in pregnancy

Jeremy P Campbell and Steve M Yentis

The two main sources of information about pre-existing conditions that result in severe morbidity in pregnancy are local or national registries/databases (e.g. UK Obstetric Surveillance System (UKOSS)) and published case series of admissions to intensive care, high-dependency or obstetric units. Information about mortality comes from registries of maternal death such as the Report of the Confidential Enquiries into Maternal Deaths in the United Kingdom, or from individual case series.

The most important pre-existing conditions likely to lead to intensive care unit (ICU) admission and/or death are cardiac disease, respiratory disease, neurological disease, psychiatric disease (including drug addiction) and haematological, connective tissue and metabolic diseases.

With increasingly successful medical care during childhood and early adulthood, the number of women with severe disease who survive to childbearing age has increased. Part of such women's desire to lead a normal life includes a wish to have children, and this places increasing demands on obstetric, anaesthetic and ICU services, as well as on women's physiological reserves.

CARDIAC DISEASE

In the UK, cardiac disease is the commonest cause of maternal death, killing more women than pre-eclampsia/eclampsia, thromboembolism and haemorrhage combined.[1] Over the last 40 years, there has been a shift away from acquired cardiac disease (mainly rheumatic heart disease) towards congenital heart disease as modern techniques of cardiac surgery in early life enable female babies with previously fatal conditions to reach maturity.[2] More recently, there has been an increase in the prevalence of ischaemic heart disease resulting from increased obesity, maternal age and smoking.

Mortality varies from less than 1% in uncomplicated conditions to over 40% in Eisenmenger's syndrome, even with modern methods of medical management.[3]

PHYSIOLOGY AND PATHOPHYSIOLOGY

The physiological changes of pregnancy most important to cardiac disease are:

- aortocaval compression
- reduction in systemic vascular resistance
- increased cardiac output (40–50% by the 20th week of gestation, with a further increase of up to 50% during labour).

In patients whose cardiac function is already impaired, inability to increase their cardiac output may result in cardiac failure. If there is a large right-to-left shunt, the fall in systemic vascular resistance results in blood bypassing the lungs. This, together with increasing maternal and fetal oxygen requirements and decreased maternal pulmonary reserve, may lead to severe exacerbation of hypoxaemia.

ANTEPARTUM MANAGEMENT

It is important that women with severe cardiac disease are appropriately counselled before pregnancy since the risks both to them and to their fetuses may be considerable. This early counselling should include anaesthetic input.

Women with cardiac disease must be assessed regularly throughout pregnancy. Electrocardiography, chest X-ray and echocardiography are the most useful investigations. For patients with valve lesions, echocardiographic measurement of valve areas provides a consistent measure of severity since flow gradients across stenosed valves usually increase in pregnancy because of the increase in cardiac output that occurs. Pulse oximetry is a simple, non-invasive tool for monitoring the degree of right-to-left shunt and can easily be repeated during pregnancy. Measures may be taken to reduced cardiac workload, for example by reducing activity and treating arrhythmias and/or cardiac failure. Prophylaxis against thromboembolism should be considered since patients with cardiac disease are more at risk, especially if confined to prolonged bed rest.[4] Low-molecular-weight heparins are now standard for prophylaxis. Heparin requirements increase with body weight, so it is vital to ensure that heparin dosing is adequate.

An obstetric and anaesthetic delivery plan should be prepared, taking into account different scenarios such as vaginal delivery and caesarean section, and the intensivists informed of the anticipated delivery date.

PERIPARTUM MANAGEMENT

The overall aim of peripartum management of the patient with cardiac disease is to minimise stress on the maternal heart and to maintain cardiac output and placental and fetal circulations. In the past, elective caesarean section (traditionally under general anaesthesia) was advocated, but the stresses and complications of surgery are now felt to exceed those of a well-controlled vaginal delivery. Therefore, over the last decade there has been a move towards vaginal delivery unless caesarean section is indicated for obstetric reasons.

Low-dose epidural analgesia regimens using weak solutions of local anaesthetic (e.g. 0.1% bupivacaine or less) with opioids such as fentanyl have been found to be effective and cardiostable.[5] Combined spinal–epidural analgesia using similar low concentrations is also suitable, and continuous spinal analgesia has also been described. In patients with marked exercise intolerance, instrumental delivery using forceps or ventouse is usually indicated to limit pushing during the second stage of labour. If a caesarean section is required, either regional or general anaesthesia has been advocated[6,7] so long as due care is taken.

Peripartum complications may be tolerated poorly by patients with limited reserves. Common peripartum complications are listed in **Box 65.1**.

The cardiovascular effects of oxytocin analogues (e.g. Syntocinon®) include a decrease in mean arterial pressure due to a fall in systemic vascular resistance and an increase in heart rate, stroke volume and cardiac output.[8] Although these are usually tolerated in healthy patients, they may cause profound hypotension in patients with limited cardiac reserves, with a worsening of shunt in susceptible individuals. If oxytocin is required, it should be diluted and given very slowly (e.g. 5 units infused over 10–20 minutes). In patients with fixed cardiac outputs and no pulmonary hypertension, ergometrine may be preferable. Withholding oxytocin altogether may be problematic because such patients may also be sensitive to the effects of acute blood loss. At caesarean section, mechanical compression of the uterus with a 'brace' suture may be used to reduce or avoid the need for oxytocics.[9]

Box 65.1 Common peripartum problems in patients with pre-existing cardiac disease

- Arrhythmias
- Cardiac failure/pulmonary oedema
- Pulmonary embolism
- Bacterial endocarditis
- Increased susceptibility to the effects of haemorrhage
- Increased risk of cardiovascular collapse in response to iatrogenic reductions in systemic vascular resistance (e.g. regional anaesthesia, intravenous bolus of oxytocin)
- Myocardial ischaemia (certain lesions)
- Increased risk from air embolism (certain lesions)

Monitoring ranges from simple non-invasive methods to peripheral arterial, central venous and pulmonary arterial cannulation, depending on the severity of the underlying disease. Central venous cannulation is often difficult because of the increased soft tissues and fluid retention of pregnancy, and the inability to lie flat, let alone head-down. Meticulous attention must be paid to avoiding intravascular air in patients with right-to-left shunts because of the risk of systemic embolism.

The principles of haemodynamic support are generally the same as in non-pregnant patients. The physiological changes of pregnancy should be remembered, especially tachycardia and increased cardiac output. Aortocaval compression must be avoided at all times, with the woman placed in the lateral or supine wedged position. The propensity for pregnant women to acute pulmonary oedema if overloaded with fluid should also be borne in mind. Exacerbation of right-to-left shunt is manifested by worsening hypoxaemia and may be improved by vasoconstrictors such as phenylephrine. If a pregnant woman requires intensive care before the baby is born, there may be a conflict between the maternal need for vasopressors and/or inotropes and the adverse effects of these drugs on uteroplacental blood flow. Similarly, attempts to prolong pregnancy with steroids and β_2-adrenergic agonists such as terbutaline or salbutamol may cause adverse cardiovascular effects (primarily pulmonary oedema) in the mother.

POSTPARTUM MANAGEMENT

Women continue to be at risk from bleeding, arrhythmias and cardiac failure postpartum. Monitoring in an area able to provide high-dependency care is vital.[10] Several problems need to be considered:

- Postoperative analgesia must be adequate.
- If oxytocin has been withheld, postpartum haemorrhage may become a problem.
- Thromboembolic prophylaxis should be (re)started.
- Prophylactic antibiotics against endocarditis should be considered (typically amoxicillin and gentamicin, or vancomycin if the woman is allergic to penicillin). Although recent guidelines suggest these are not necessary for routine use in women with cardiac disease,[11] many clinicians caring for such women give them, after weighing up the individual risks and benefits.
- There should be a high index of suspicion and aggressive early management of infection (especially of the chest, wound and genital tract).

The duration of postpartum observation will depend on the underlying disease. In Eisenmenger's syndrome, sudden death typically occurs 1–2 weeks after delivery from pulmonary embolism and/or pulmonary haemorrhage.[12]

RESPIRATORY DISEASE

The most common pre-existing respiratory diseases that cause mothers to present to ICUs are asthma and cystic fibrosis.

Asthma is very common but rarely causes serious morbidity in its own right, although there is a higher risk of several complications of pregnancy and neonatal morbidity.[13]

Cystic fibrosis is comparatively rare, but recent advances in its management have resulted in many young women achieving successful pregnancies with excellent maternal and fetal outcomes.[14] Pregnancy per se does not appear to confer an increased risk of maternal mortality or accelerate decline in lung function. Risk factors are the same as in non-pregnant patients: pre-pregnancy forced expiratory volume in 1 second (FEV_1) <60% of predicted, colonisation with *Burkholderia cepacia*, pancreatic insufficiency, and diabetes mellitus. Successful pregnancy following lung transplantation may be possible. Pre-pregnancy counselling and psychological support are important considerations since the decision to have a child, with the risk of passing on the cystic fibrosis gene, is one that imposes a great deal of stress on the mother, her partner and their relatives.

PHYSIOLOGY AND PATHOPHYSIOLOGY

If respiratory function is already impaired, the physiological effects of pregnancy add an additional burden on the respiratory system that may precipitate respiratory failure. These include:

- reduced functional residual capacity
- increased oxygen demand
- increased minute ventilation ($PaCO_2$ in late pregnancy is typically 27–32 mmHg (3.6–4.3 kPa) compared with 40 mmHg (5.3 kPa) in the non-pregnant state.

In addition, chronic hypoxaemia may lead to pulmonary vasoconstriction, pulmonary hypertension and cor pulmonale. In cystic fibrosis, an additional stress is the increased nutritional demand in a patient who may already be malnourished because of malabsorption. The increased minute ventilation in late pregnancy should be borne in mind when interpreting arterial blood gases: an arterial partial pressure of carbon dioxide of 45 mmHg (6 kPa) represents a much greater deviation from the normal value in pregnancy than in non-pregnant patients.

GENERAL MANAGEMENT AND COMPLICATIONS

Antepartum management comprises regular assessment and adjustment of medical treatment if required. Patients may be taking a variety of drugs, including steroids. Chronic use of steroids may be associated with impaired glucose tolerance in pregnant patients.

Regional analgesia is indicated in patients with moderate or severe functional limitation in order to reduce the demands of labour. If caesarean section is required, regional anaesthesia is thought to reduce the risk of pulmonary complications, although women with severe respiratory disease may be unable to lie flat. Care must be taken to ensure that the regional anaesthetic block does not extend too high as this may impair the woman's ability to breathe and cough.

In cystic fibrosis, the principles of intensive care are generally the same as in non-pregnant patients. The mainstay of treatment is regular physiotherapy and antibiotic therapy. It is important to know whether the patient has been previously colonised with unusual and/or resistant organisms (e.g. *Burkholderia cepacia*). The biggest single hazard for the mother is an acute infective exacerbation in the second or third trimester provoking respiratory failure. Infection must be treated early and aggressively. Respiratory failure has been managed with non-invasive ventilatory techniques with some success. Delivery of the fetus usually results in an immediate improvement in maternal oxygenation, although pain following caesarean section may limit deep inspiration and the ability to cough, encouraging basal atelectasis and retained secretions. Continuing respiratory support postpartum therefore remains essential.

NEUROLOGICAL DISEASE

Epilepsy is the most frequent pre-existing neurological disorder in pregnancy and remains an important cause of maternal death, often related to poor seizure control as a result of altered pharmacodynamics and pharmacokinetics of anticonvulsant drugs in pregnancy.[1] Neurological conditions that potentially affect respiratory function (e.g. myasthenia gravis, multiple sclerosis, high spinal cord lesions) can be expected to cause particular problems in pregnancy.

GENERAL MANAGEMENT

Traditionally, regional analgesia and anaesthesia were avoided in most neurological diseases for fear of exacerbating the condition, or being blamed for an exacerbation should it occur. Nowadays, most authorities encourage regional analgesia for labour in parturients at risk of respiratory insufficiency secondary to their neurological condition since it reduces the physiological demands of labour. Similarly, regional anaesthesia for caesarean section avoids the problems of postoperative sedation, and whether or how to use neuromuscular-blocking drugs. Initial fears about an increased relapse rate in multiple sclerosis following regional anaesthesia have fortunately not been borne out by a large prospective series.[15]

If there is raised intracranial pressure, the use of regional techniques is more controversial. Although

Table 65.1 Guide to converting oral to systemic medication in mothers with myasthenia gravis*

DRUG	ORAL DOSE (MG)	INTRAMUSCULAR DOSE (MG)	INTRAVENOUS DOSE (MG)
Neostigmine	15	0.7–1.0	0.5
Pyridostigmine	60	3–4	2

*Approximate conversion doses are given.

labour and vaginal delivery without effective analgesia can result in marked increases in intracranial pressure, accidental dural puncture is potentially disastrous. Even if successfully placed, rapid epidural injection may be associated with increases in intracranial pressure.[16]

Management of conditions in which there are spinal abnormalities is also controversial. Spinal bifida and other spinal cord lesions have been successfully managed using regional techniques, although a careful balance between risk and benefit must be achieved in each case. These patients are unlikely to present to intensivists unless they are associated with respiratory impairment.

Myasthenia gravis poses a particular problem because of the need for regular medication throughout labour and after delivery. Gastric emptying may be decreased during labour, especially if the mother has been given systemic opioids. It is therefore important to consider parenteral administration of anticholinesterase therapy during this period. A useful guide is given in **Table 65.1**. Epidural analgesia can be helpful in limiting maternal fatigue during labour. The mother should be observed for signs of increasing weakness for up to 10 days postpartum.

PSYCHIATRIC DISEASE (INCLUDING DRUG ADDICTION)

Psychiatric disorders are common in pregnancy and after delivery, and recent maternal mortality reports have highlighted suicide and the complications of drug addiction as relatively common causes of maternal death.[1] Patients with psychiatric disease may be more vulnerable to becoming pregnant, and pregnant women are more likely to suffer from psychiatric disease during and/or after pregnancy.

Abuse of drugs poses similar problems to those in the non-pregnant population, with the additional effects of fetal addiction and growth retardation. In particular, cocaine abuse has been implicated in causing placental abruption and maternal convulsions, hypertension and tachycardia, with increasing morbidity and mortality for both mother and fetus.[17] Unplanned operative intervention is more likely, and these patients may require admission to ICU postoperatively.

Intensive care management is usually similar to that in non-pregnant patients. If antepartum, the effects of drugs (both those taken in overdose and their antidotes) on the fetus should be considered.

HAEMATOLOGICAL, CONNECTIVE TISSUE AND METABOLIC DISEASES

Several haematological conditions may predispose to critical illness in pregnancy, the commonest being sickle cell disease. In general, ICU management of patients with haematological disease is as for non-pregnant patients.

Connective tissue disease rarely presents to the intensivist unless there is systemic involvement resulting in cardiac and respiratory insufficiency. These may be exacerbated by the physiological demands of pregnancy. Such patients are also at increased risk of obstetric complications such as haemorrhage.

Diabetes mellitus is the most important pre-existing metabolic disease in pregnancy and is well known to increase both maternal and fetal morbidity. It usually presents in the ICU as diabetic ketoacidosis, or as a contributory factor to other conditions (e.g. sepsis). Anecdotal reports suggest that diabetic ketoacidosis in pregnancy may be particularly difficult to treat and stability of blood glucose may be achieved only after delivery of the fetus.

Anaphylaxis

Malcolm M Fisher

Anaphylaxis is a symptom complex accompanying the acute reaction to a chemical recognised as hostile. In the classical reaction the patient has been previously sensitised (immediate hypersensitivity or type 1 hypersensitivity), although the sensitising agent may be unknown. The term 'anaphylactoid reaction' is used to describe reactions clinically indistinguishable from anaphylaxis, in which the mechanism is non-immunological, or has not been determined. Recent consensus meetings have suggested the use of the term 'anaphylactoid' be discontinued and 'anaphylaxis' used to describe the symptom complex which may be either 'non-immune' or 'immune',[1] but the 'new' terminology has not been generally accepted. The clinical signs of anaphylaxis may be produced by direct drug effects, physical factors or exercise, and a causative agent cannot always be determined. The mediators involved are the same as those in other acute inflammatory responses such as sepsis, but the rate of release is more rapid and of shorter duration.

AETIOLOGY

Clinical anaphylaxis in hospital commonly follows injection of drugs, blood products, plasma substitutes, contrast media, or exposure to latex products or chlorhexidine. Outside hospital, ingestion of foods or food additives (especially peanut products) or insect stings may be more common causes than drugs.

Neugut et al[2] estimated 1400–1500 deaths per year in the USA and between 3.3 and 40.9 million patients at risk. They estimated radiocontrast media and penicillin to be the greatest causes of death, with food and stings the next groups. In contrast a postmortem study of 56 deaths in the UK[3] attributed 19 deaths to venoms, 16 to foods and 19 to drugs and radiocontrast media.

In anaphylaxis, sensitisation occurs following exposure to an allergenic substance, which either alone, or by combination with a protein or hapten, stimulates the synthesis of immunoglobulin E (IgE). Some IgE binds to the surface of mast cells and basophils. Later, re-exposure to antigen produces an antigen–cell surface IgE antibody interaction where two IgE molecules are bridged. This results in mast cell degranulation, and the release of histamine and other mediators, including interleukin, prostaglandins and platelet-activating factor. Histamine is responsible for the early signs and symptoms, but is rapidly cleared from plasma. The overall effects of the mediators are to produce vasodilatation, smooth-muscle contraction, increased glandular secretion and increased capillary permeability. The mediators act both locally and upon distant target organs.

Anaphylactoid reactions may be due to a direct histamine-releasing effect of drugs or other triggers on basophils and mast cells. The symptom complex may also be produced by other mechanisms. Some intravenous drugs and X-ray contrast media may activate the complement system. Plasma protein and human serum albumin reactions may be induced by either albumin aggregates or stabilising agent-modified albumin molecules. Other reactions, including those to dextrans and gelatin preparations, may be activated by non-IgE antibody already present in the plasma or osmotic factors (dextrose, mannitol).

The direct histamine-releasing effects of some drugs may produce reactions due to the effect of histamine alone, and such reactions are related to volume, rate and amount of infusion. Recent work suggests that the site of release of histamine may be important in its clinical effects. Drugs such as morphine and Haemaccel release histamine from skin alone,[4] and are unlikely to produce symptoms such as bronchospasm, whereas drugs which produce release from lung mast cells (e.g. atracurium, vecuronium and propofol) may be more likely to produce bronchospasm.[5] Direct histamine release is usually a transient phenomenon, but in some patients severe manifestations may occur, particularly with Haemaccel and vancomycin.

Anaphylactic reactions are usually seen in fit and well patients. It is likely that the adrenal response to stress 'pretreats' sick patients, and blocks the release and effects of anaphylactic mediators. The exception to this appears to be patients with asthma, in whom reactions to the additives in steroid and aminophylline preparations may occur, and this may be related to the reduced catecholamine response in asthma.[6] Patients on beta blockers and with epidural blockade may be more likely to develop adverse responses due to histamine release, and this may also be related to reduced catecholamine responsiveness. Reactions occurring in these groups are more difficult to treat.

CLINICAL PRESENTATION

The latent period between exposure and development of symptoms is variable, but usually occurs within 5 minutes if the provoking agent is given parenterally. Reactions may be transient or protracted (lasting days), and may vary in severity from mild to fatal. Recurrent anaphylaxis is described. Cutaneous, cardiovascular, respiratory or gastrointestinal manifestations may occur singly or in combination.

Cutaneous features include piloerection, erythematous flush, generalised or localised urticaria, angioneurotic oedema, conjunctival injection, pallor and cyanosis. Awake patients may experience an aura, warning of an impending reaction. Cardiovascular system involvement occurs most commonly and may occur as a sole clinical manifestation.[7] It is characterised by initial bradycardia then sinus tachycardia, hypotension and the development of shock.

In patients reacting due to venom desensitisation, bradycardia may be severe and require treatment.[8] Respiratory manifestations include rhinitis, bronchospasm and laryngeal obstruction. Gastrointestinal symptoms of nausea, vomiting, abdominal cramps and diarrhoea may be present. Other features include apprehension, metallic taste, choking sensation, coughing, paraesthesiae, arthralgia, convulsions, clotting abnormalities and loss of consciousness. Pulmonary oedema is a rare sign. Rarely, some women develop a profuse, watery, vaginal discharge 3–5 days after anaphylaxis. It is self-limiting.

Anaphylaxis is rare in the intensive care unit (ICU), probably because of the protective effects of the adrenal response to stress. However, use of the mast cell tryptase assay (see below) may detect anaphylaxis as an unsuspected cause of shock in intensive care.

PATHOPHYSIOLOGY OF CARDIOVASCULAR CHANGES

The traditional concept of the cardiovascular changes in clinical anaphylaxis is that of an initial vasodilatation, followed by capillary leak of plasma, which produces endogenous hypovolaemia, reduced venous return and lowered cardiac output.

Whether or not cardiac function is impaired has been controversial. Although most anaphylactic mediators adversely affect myocardial function in vitro, most case reports of anaphylaxis in which invasive cardiovascular monitoring has been used suggest minimal impairment of cardiac function. Patients with normal cardiac function before the reaction rarely show evidence of cardiac failure or arrhythmias other than supraventricular tachycardia, but the incidence of serious arrhythmias and cardiac failure increases in those with prior cardiac disease.[7] Echocardiography in anaphylaxis usually shows an 'empty', normally contracting heart. Troponins are elevated after anaphylaxis, but these elevations do not normally predict coronary artery disease requiring intervention. A recent study of patients with anaphylaxis during venom desensitisation showed that bradycardia requiring treatment was a common finding.[8] Two reactions in patients with no previous cardiac disease, where the major manifestation was prolonged global myocardial dysfunction, and the use of a balloon counterpulsator was life-saving, have been reported.[9]

TREATMENT

There are no randomised controlled trials of treatment in anaphylaxis, and the unexpected onset, rapid course and usual rapid response to treatment preclude performing such trials. Treatment recommendations are based on historical practice, case reports, series of cases and animal models.

OXYGEN

Oxygen is given by facemask. Endotracheal intubation may be required to facilitate ventilation, especially if angioedema or laryngeal oedema is present. Oedema of the upper airway is more common when anaphylaxis is due to foods than to drugs.[3] Mechanical ventilation is indicated for severe bronchospasm, apnoea or cardiac arrest.

EPINEPHRINE (ADRENALINE)

Epinephrine is universally recommended as the drug of choice for severe reactions. In the community epinephrine may be given intramuscularly in a dose of 0.3–1.0 mg early in anaphylaxis. Intramuscular epinephrine produces higher levels earlier in stable allergic patients than subcutaneous epinephrine.[10] In severe shock or in patients in whom muscle blood flow is thought to be compromised by shock, intravenous injection of 3–5 ml of 1:10 000 epinephrine is given. A second dose is necessary in 35%[11] and an infusion in 10%.

Epinephrine, by increasing intracellular levels of cyclic adenosine monophosphate (cAMP) in leukocytes and mast cells, inhibits further release of histamine. It has beneficial effects on myocardial contractility, peripheral vascular tone and bronchial smooth muscle, and stabilises mast cells. A common management error is not to institute external cardiac massage (ECM) as the arrhythmia is 'benign'. If the patient is pulseless, ECM should be instituted irrespective of rhythm, although there are no data to support its efficacy.

There has been controversy regarding the best route of administration of epinephrine outside hospital. Both case reports and patients self-injecting show efficacy for

intramuscular epinephrine when given early. Intravenous epinephrine may rarely cause arrhythmias and myocardial infarction, particularly in unmonitored patients. In our series it seems to be more hazardous when the diagnosis of anaphylaxis is incorrect. Recent recommendations endorse the use of intramuscular epinephrine.[12]

OTHER SYMPATHOMIMETIC AMINES

Other sympathomimetic drugs may reverse the symptoms, but appear (albeit in the absence of any randomised trials) to be less effective than epinephrine. Norepinephrine by infusion may be life saving in the absence of a response to fluid loading and epinephrine. Methoxamine and phenylephrine have been used to treat anaphylactic hypotension successfully as first-line treatment and in 'rescue' therapy when epinephrine appears ineffective. More recently, case reports have shown vasopressin and methylene blue to be effective in refractory cases of hypotension.

COLLOIDS

Plasma expanders are given rapidly to correct the hypovolaemia consequent to acute vasodilatation and leakage of fluid from the intravascular space.[13] The author favours plasma protein solution or gelatin preparations rather than crystalloids, as they remain in the vascular compartment earlier and for longer. There are, however, no data showing improved outcomes from colloid over crystalloid, and there are many patients who have been successfully resuscitated with crystalloid alone. Greater volumes of crystalloid are necessary and on occasions very large volumes of fluid may be required; central venous pressure monitoring and measurement of haematocrit are helpful.

BRONCHOSPASM

Epinephrine should be given. Nebulised salbutamol should be given for severe asthma. Aminophylline 5–6 mg / kg intravenously may be given over 30 minutes, if bronchospasm is unresponsive to epinephrine alone. Aminophylline increases intracellular cAMP by phosphodiesterase inhibition, and its effect on inhibiting histamine and interleukin release is theoretically additive to that of epinephrine. Adverse responses have not been observed in our series but a recent comprehensive review[14] suggested safer agents with proven efficacy should be preferred. Volatile anaesthesia, ketamine and magnesium sulphate may produce improvement in some patients with severe asthma.

CORTICOSTEROIDS

Steroids have no proven benefit, particularly early, and should be reserved for refractory bronchospasm. Conversely, steroids are often given and there is no evidence of harm.

ANTIHISTAMINES

Antihistamines are the treatment of choice in localised non-severe reactions. In severe reactions they are only indicated in protracted cases or in those with angioneurotic oedema, which may recur. The data on antihistamines are not conclusive, but in protracted anaphylaxis, improvement is often reported with H_2-blockers.

A comprehensive review of the evidence for efficacy and recommendations from the evidence has recently been produced by the World Allergy Organisation.[15]

DIAGNOSIS

The most important advance in the diagnosis of anaphylaxis has been the introduction of an assay for mast cell tryptase. The mast cell enzyme is elevated 1 hour after a reaction begins, and the elevation may persist for up to 4 hours. It can also be helpful in the diagnosis of anaphylaxis from postmortem specimens.[16] The assay is highly specific and sensitive for anaphylaxis, although elevated levels are found with direct histamine release, and at postmortem in some patients with myocardial infarction. A negative mast cell tryptase assay does not exclude anaphylaxis as the diagnosis. Mast cell tryptase has been used to diagnose anaphylaxis postmortem.

FOLLOW-UP

Following successful acute management, the drug or agent responsible should be determined by in vitro or in vivo testing if possible. Hyposensitisation should be considered for food, pollen and bee venom allergy. A medic alert bracelet should be worn and the patient should be given a letter stating the nature of the reaction to the particular causative agent.

If re-exposure to the allergen is likely at home, patients or their relatives should be instructed in the use of epinephrine, salbutamol inhalation and antihistamines. Clinical anaphylaxis may be modified by pretreatment with disodium cromoglycate, corticosteroids, antihistamines, salbutamol and isoprenaline.

In patients with recurrent anaphylaxis in whom no cause can be found corticosteroids on alternate days reduce the incidence and severity of attacks.

Host defence mechanisms and immunodeficiency disorders

Steven McGloughlin and Alexander A Padiglione

The outcome of an infection is determined by the balance between our ability to eliminate an invading microorganism and that microorganism's virulence. Diverse host defence mechanisms protect the different anatomical compartments of the body from a great variety of microorganisms. In particular there is a coordinated immunological response to infection, involving both cellular and humoral components. The immune system can be defective in many ways, leading to an increased propensity to infections. The response also needs to be controlled to avoid inappropriate and excessive activation, such as when excessive systemic activation results in disseminated intravascular coagulation (DIC).

INNATE IMMUNE RESPONSES

Innate immune responses provide a first line of defence against many microorganisms, capable of reacting without prior exposure to antigens from those microorganisms. This innate immune system consists of plasma proteins, including alternative-pathway components of the complement system and mannose-binding lectin (MBL), some lymphocytes with cytotoxic activity (natural killer or NK cells) and some macrophage functions.

ACUTE-PHASE REACTION

The acute-phase reaction is a response of the haematopoietic and hepatic systems, involving many plasma proteins and the cellular components of the blood. It occurs within hours of acute physical stress or infection. Most of the proteins are inflammatory mediators or inhibitors of transport proteins. Fibrinogen, the bulk protein of the coagulation system, is one of the plasma proteins to show the greatest rise in the acute-phase reaction, and is responsible for the elevation in the erythrocyte sedimentation rate. Decreases in haemoglobin, serum iron and albumin are all normal in the acute-phase reaction. The fall in albumin is due to redistribution and decreased synthesis and generally does not require supplementation. The function of many acute-phase proteins remains unclear, but may be beneficial to the patient.

THE ADAPTIVE IMMUNE SYSTEM

Adaptive immune responses exhibit specificity, memory, amplification and diversity. This specificity (immune response against a particular antigen) and memory (prompt response on subsequent exposures) is mediated by antigen receptors on the surface of lymphocytes. Amplification and diversity of immune responses are regulated by cytokines, which are secreted by lymphocytes and other cells, and through the effects of various lymphocyte surface molecules, including adhesion molecules and co-stimulatory molecules. Cytokines have various activities, the most important of which are cell activation (e.g. interferon gamma (IFN-γ)), regulation of immune responses (e.g. interleukin (IL)-10) and pro-inflammatory effects (e.g. tumour necrosis factor (TNF)) and lymphotoxins).

ANTIGEN PRESENTATION AND THE ROLE OF T AND B LYMPHOCYTES

An adaptive immune response is initiated by the processing and presentation of fragments of a microorganism in a form that makes them antigenic to lymphocytes. Major histocompatibility complex (MHC) class I (human leucocyte antigen (HLA)-A, B, C) and class II (HLA-DR, DP, DQ) molecules are the major cell-surface antigen presentation molecules, and determine the nature of the subsequent response against the antigen.

Class I MHC molecules are present on most nucleated cells, and present processed *endogenous* peptides (such as fragments of viruses) to the T-cell receptor (TcR) of CD8+ (cytotoxic) T lymphocytes. Activated CD8+ T cells have a cytotoxic effect on the presenting cell, resulting in the death of the cell and inhibition of viral replication.

Class II MHC molecules are found on macrophages and monocytes (where they present fragments of phagocytosed microorganisms to TcRs on CD4+ (helper) T cells) and B cells (where antigen is bound to specific surface immunoglobulins, the B-cell antigen receptor).

Activation of CD4+ T cells by these *exogenous* antigens results in the expression of cell-surface molecules

and secretion of cytokines with immunoregulatory effects. These immunoregulatory molecules augment the functions of many other cells, including B cells, T cells and macrophages (T-cell help). CD4+ T-cell activation may also elicit macrophage activation (critically dependent on the production of IFN-γ) to assist in killing of the microorganism.

Proliferating B cells differentiate into plasma cells, which secrete immunoglobulins with antibody activity against the initiating antigen, or into memory B cells, which live for a long time and rapidly respond on re-exposure to an antigen.

IMMUNOGLOBULINS AND ANTIBODIES

Nine isotypes of immunoglobulin can be produced, each of which has a different function. Immunoglobulin M (IgM) is a large pentamer that has its major effect within the circulation early in the immune response, and works as a bacterial agglutinator and complement activator. IgA_1 and IgA_2 are produced at secretory surfaces, such as the mucosa of the gut and respiratory tract, and also in the breast, where IgA is a major constituent of colostrum and provides secretory antibody to the gut of the neonate. IgE is also produced at mucosal surfaces and is an important part of the immune response against parasitic infections. IgD acts mainly as a B-cell receptor. IgG occurs in four subclasses, and is the only antibody able to cross the placenta: IgG_1 and IgG_3 are particularly effective at activating complement and binding to Fc receptors on phagocytic cells; IgG_2 are mainly active against polysaccharide antigens, such as those present in bacterial cell walls; the functions of IgG_4 antibodies are unclear.

SECONDARY ANTIBODY FUNCTION

Antibodies must act through one of several secondary effector mechanisms to eliminate a micro-organism. Antibodies complexed with antigens can activate the complement system through the classical pathway. The complement system may also be activated directly by components of microorganisms through the alternative (or MBL) pathway. Activation of the complement system results in the generation of biologically active molecules, such as C3b, which is an important opsonin, and the activation of the membrane attack complex (MAC), which lyses bacterial cell walls. Like C3b, antibodies of the IgM, IgG_1 and IgG_3 isotypes are also important opsonins. These molecules, when bound to the surface of a microorganism, facilitate their opsonisation and phagocytosis. These effects of complement and antibody are mediated through complement receptors (CRs) and receptors for the Fc portion of the immunoglobulin molecules (Fc receptors) on the surface of phagocytic cells such as neutrophils and macrophages.

DIVERSITY OF IMMUNE RESPONSES

The type of immune response produced against a microorganism varies according to the nature of the infecting organism. Thus virus-infected cells elicit a cytotoxic CD8+ T-cell response; intracellular pathogens such as mycobacteria and protozoa elicit a CD4+ T-cell response, which results in macrophage activation; encapsulated bacteria elicit an opsonising antibody response; other bacteria such as *Neisseria* spp. elicit a complement-activating antibody response, which lyses the cell wall of the bacterium. The nature of the immune response is regulated by cytokines, which provide T-cell help (Th) in the course of an immune response. Thus IL-2, IL-12 and IFN-γ production induces a predominantly cellular immune response (Th1), whereas the production of IL-4 and IL-13 induces a predominantly antibody-mediated immune response (Th2).

IMMUNODEFICIENCY DISORDERS

Immunodeficiency disorders can generally be classified functionally into five groups: antibody deficiency, complement deficiency, cellular immunodeficiency, phagocyte dysfunction and combined immunodeficiency (T cells, B cells and NK cells).

Immunodeficiency disorders may also be classified aetiologically as either primary or acquired.

Primary immunodeficiency disorders are the result of a developmental anomaly or a genetically determined defect of the immune system. Primary immunodeficiency due to an absent or non-functional gene product critical for the normal immune function is more severe, so it tends to present early in life. Primary immunodeficiency due to aberrant regulation of lymphocyte differentiation, which is probably determined by the products of several genes and may be influenced by environmental factors, tends to be less severe so it presents later. Our understanding of the genetic basis of many of these conditions is improving, including a number of specific gene defects that lead to selective susceptibility to single pathogens.

Acquired immunodeficiency disorders are more common than primary immunodeficiency disorders and may present at any time after early childhood. Most result from an immune defect that is a consequence of a disease process, infection or complication of a therapeutic procedure such as splenectomy, immunosuppressant therapy or haemopoietic stem cell transplantation (HSCT).

An immunodeficiency disorder may be considered in an adult patient with an unexplained abnormal propensity to infections, such as recurrent or multiple serious infections (e.g. deep abscess, meningitis, osteomyelitis, sepsis, pneumonia), persistent thrush, opportunistic infections or poor response to antimicrobial therapy, and requires the demonstration of a specific immune defect (**Table 67.1**).

Table 67.1 Tests of immunocompetence

IMMUNE DEFICIENCY SYNDROME	CLINICAL MANIFESTATION	TESTS
Antibody-mediated	Recurrent bacterial infection, especially with encapsulated bacteria, e.g.: *Streptococcus pneumoniae* *Neisseria meningitides* *Haemophilus influenzae*	Immunoglobulin G, A and M levels IgG subclasses Peripheral blood B-cell count (CD 19) *Consider:* Immunisation response to: Polysaccharide antigens (e.g. pneumococcal, pre and post vaccination) Protein antigens (e.g. tetanus and diptheria antibodies)
Cell-mediated immunity	Predominantly intracellular pathogens: Viruses Herpes simplex viruses Cytomegalovirus Varicella-zoster virus Epstein–Barr virus Molluscum contagiosum virus JC virus (cause of progressive multifocal leucoencephalopathy) Mycobacteria *Mycobacterium tuberculosis* Non-tuberculous mycobacteria Bacterial *Salmonella* spp. *Shigella* spp. *Listeria monocytogenes* Fungi and yeasts *Candida* spp. (mucosal infections) Cryptococci *Aspergillus* spp. Protozoa *Toxoplasma gondii* Cryptosporidia *Pneumocystis jiroveci*	Peripheral blood T-cell subsets (CD3+, CD4+ and CD8+) Serology for HIV (+/– HTLV) *Consider:* T-cell response to antigens Cytokine assays Delayed-type hypersensitivity (DTH) skin test responses to antigens (rarely done now)
Phagocyte function	Recurrent severe bacterial infection, esp. *Neisseria meningitides*	Neutrophil count *Consider:* Tests of oxidative killing mechanisms, e.g. nitroblue tetrazolium reduction test (NBT) *or* dihydrorhodamine oxidation Neutrophil migration assays Bacteria *or Candida* killing assays
Complement system	*Streptococcus pneumoniae* *Neisseria meningitides* *Moraxella* spp. *Acinetobacter* spp.	Immunochemical quantitation of C3 and C4 Functional assay of the classical pathway (CH50) *Consider:* Functional assay of the alternative pathway (AH50) Immunochemical quantification of other individual components

ANTIBODY DEFICIENCY

A poor systemic antibody response most commonly results in a lack of opsonising antibody, and a propensity to infections with encapsulated bacteria such as *Streptococcus pneumoniae* or *Haemophilus influenzae*, most often manifesting as recurrent respiratory tract infections including sinusitis. Chronic echovirus infections of the nervous system and infection with some mycoplasmas may also occur in patients with severe primary immunoglobulin deficiency (agammaglobulinaemia).

PRIMARY ANTIBODY DEFICIENCY DISORDERS

Failure of B-cell production or differentiation is the cause of most primary antibody deficiency disorders.[1] B cells are absent from blood and secondary lymphoid tissues in patients with X-linked agammaglobulinaemia (XLA) because mutations of the *Btk* gene on the X-chromosome result in the absence of a B-cell tyrosine kinase necessary for the maturation of pre-B cells to B cells in the bone marrow. In the hyper-IgM immunodeficiency syndrome, B cells are able to differentiate into plasma cells secreting IgM, but not IgG or IgA.

Common variable immunodeficiency (CVID) is a group of disorders that appear to be the consequence of immunoregulatory defects that result in impaired B-cell differentiation, leading to hypogammaglobulinaemia.

IgA deficiency also results from impaired B-cell differentiation. Deficient secretory antibody responses are common in patients with IgA deficiency, but most affected individuals are able to produce compensatory secretory IgM or IgG antibody responses and do not suffer from infections. Some may also have a defect of systemic antibody responses, such as an IgG subclass deficiency and/or impairment of antibody responses to polysaccharide antigens, and hence may suffer from recurrent infections.[2]

The immunoregulatory defect underlying CVID and IgA deficiency sometimes results in an increased propensity to autoimmunity. This can include the production of anti-IgA antibodies, which may result in anaphylactoid reactions to blood products containing IgA.

ACQUIRED ANTIBODY DEFICIENCY DISORDERS

B-cell chronic lymphocytic leukaemia or lymphoma and myeloma are commonly associated with reduced synthesis of normal immunoglobulins, which may result in bacterial infections.[3] A thymoma is a rare cause of immunoglobulin and antibody deficiency, and should be considered in a patient presenting with primary immunoglobulin deficiency after the age of 40.[4] Asplenic patients have impaired production of antibodies against polysaccharide antigens leading to infection with encapsulated bacteria, such as pneumococci and meningococci, particularly in patients who have haematological malignancy.[5]

Drugs occasionally affect B-cell differentiation and cause immunoglobulin deficiency, particularly IgA deficiency. The most common offender is phenytoin. Most patients do not have antibody deficiency severe enough to cause infections. Intensive plasmapheresis may also cause severe immunoglobulin deficiency if immunoglobulin replacement is not used.

TREATMENT OF ANTIBODY DEFICIENCY DISORDERS

Infections can be prevented by regular infusions of intravenous immunoglobulin (IVIg) in patients with primary or acquired antibody deficiency. The usual dose is 0.4 g/kg given monthly. Acute infections should be treated with appropriate antibiotics. The routine use of IVIg as an adjunct in the management of sepsis in adults cannot be recommended, as higher-quality studies have failed to confirm earlier suggestions of benefit.

CELLULAR IMMUNODEFICIENCY

Impairment of cell-mediated immune responses leads to an increased propensity to infections normally controlled by cellular immune responses (see Table 67.1). These microorganisms are often pathogens that replicate intracellularly and cause persistent (latent) infections that reactivate when the cellular immune response against them becomes ineffective.

PRIMARY CELLULAR IMMUNODEFICIENCY

Children with the Di George syndrome have a complete or partial absence of the thymus, resulting in depletion of T cells from blood and lymphoid tissue.[6] A less severe defect of cellular immunity occurs in patients with chronic mucocutaneous candidiasis. This is usually seen in patients with the autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED) syndrome, which results from a disorder of T-cell processing in the thymus.[7]

ACQUIRED CELLULAR IMMUNODEFICIENCY

Acquired defects of cellular immunity are by far the most common cause of cellular immunodeficiency, with human immunodeficiency virus (HIV) infection the most common (see Ch. 68). Less commonly, Hodgkin's disease, T-cell lymphomas and sarcoidosis may also be complicated by opportunistic infections occurring as a consequence of cellular immunodeficiency. A thymoma is a rare cause of chronic mucocutaneous candidiasis that, like thymoma and immunoglobulin deficiency, occurs later in life.[4]

Suppression of cellular immune responses is an intended effect of many immunosuppressant drugs used to treat allograft rejection, graft-versus-host disease (GvHD), autoimmune diseases and vasculitis. Opportunistic infections may complicate this type of immunodeficiency.

TREATMENT OF CELLULAR IMMUNODEFICIENCY DISORDERS

Most infections complicating cellular immunodeficiency are re-activated latent infections, so prevention by the use of prophylactic antimicrobial drugs is important, and is best defined in HIV-induced immunodeficiency.[8] The risk and type of infection are determined by the degree and duration of cellular immunodeficiency, allowing for appropriate decisions to be made regarding investigations, treatment and prophylaxis.

Acquired cellular immunodeficiency may be corrected, at least temporarily, by removing its cause (e.g. by suppressing HIV infection or ceasing

immunosuppressive therapy). Thymus transplantation may be effective in children with thymus aplasia.

COMPLEMENT COMPONENT DEFICIENCY

Deficiency of complement components is an uncommon but often overlooked cause of recurrent bacterial infections. Complement-mediated lysis of bacterial cell walls is a critical defence against certain bacteria, especially *Neisseria* spp. and related bacteria such as *Moraxella* spp. and *Acinetobacter* spp. Deficiency of classical pathway components may also result in impaired antibody responses.

PRIMARY COMPLEMENT DEFICIENCY

Congenital deficiency of C3 is extremely rare. C3b is an important opsonin and C3 deficiency will often impair phagocytosis of bacteria, causing a propensity to severe pyogenic infections. Deficiency of MAC components is more common, and should be considered in patients with recurrent meningococcal infections.[9] Deficiency of classical pathway components (C1, C2, C4) may also result in an increased propensity to infection with meningococci and some other bacteria, but most affected individuals do not experience recurrent infections.

ACQUIRED COMPLEMENT DEFICIENCY

Disease processes that cause persistent activation of the complement system may cause depletion of complement components, particularly classical pathway components. This can result in infections with *Neisseria* spp. or related bacteria, and sometimes overwhelming septicaemia when the complement deficiency is severe. Systemic lupus erythematosus, myeloma and chronic atrioventricular shunt infections are rare causes of complement component deficiency.

MANAGEMENT OF PATIENTS WITH COMPLEMENT DEFICIENCY

An awareness of the possibility of complement deficiency is the most important aspect of management. Replacement therapy is not available. If a complement component deficiency is identified, screening of family members should be considered.

PHAGOCYTE DISORDERS

Phagocytosis of a bacterium or fungus by a neutrophil, leucocyte or macrophage is dependent on chemotaxis (attraction of phagocytes to the site of infection), adhesion (to endothelial cells via molecules such as integrins), binding (to opsonins on the microorganism), ingestion and intracellular killing (which involves both oxidative and non-oxidative mechanisms).

Depletion or functional impairment of phagocytes results in an increased propensity to bacterial and fungal infections, particularly infection with *Staphylococcus aureus*, Gram-negative enteric bacteria, *Candida* spp. and *Aspergillus* spp. Primary or acquired defects of phagocytes may result in localised pyogenic infections or pneumonia. In patients with severe neutropenia, however, localised infections may show little inflammatory reaction and overwhelming systemic infections, in particular systemic fungal and yeast infections, are common.

PRIMARY DISORDERS OF PHAGOCYTOSIS

Congenital neutropenias are rare. Defects of phagocyte function usually affect chemotaxis, adhesion or intracellular killing, either alone or in combination. The best-characterised defect of phagocyte adherence results from a congenital absence of the β-subunit of CD18 integrins in patients with leucocyte adhesion deficiency syndrome type 1.[10] Defects of intracellular killing are usually caused by a deficiency of microbicidal enzymes. Chronic granulomatous disease (CGD) results from a deficiency of a phagosome enzyme (NADPH oxidase) leading to ineffective oxidative killing.[11] CGD usually presents in childhood but may present in adults, even as late as the seventh decade. It should be considered in patients with recurrent abscesses or suppurative lymphadenitis, and in patients with pneumonia caused by *S. aureus* or *Aspergillus* spp. infection.

ACQUIRED DISORDERS OF PHAGOCYTOSIS

Severe neutropenia may be complicated by bacterial or fungal infections. There are many causes of neutropenia, including autoimmune neutropenia, drug therapy and haematological diseases such as cyclic neutropenia, myelodysplastic syndromes and aplastic anaemia. Cytotoxic chemotherapy, used to treat various malignancies, commonly causes neutropenia, which is often complicated by severe bacterial and fungal infections.

MANAGEMENT OF PHAGOCYTE DISORDERS

Acquired neutropenia may be corrected by removing the underlying cause and/or use of granulocyte colony-stimulating factor (G-CSF). Febrile neutropenia requires investigation for the source of sepsis and empirical antibiotics. If fever persists then antifungals should be added. IFN-γ therapy may be effective in patients with CGD.

COMBINED IMMUNODEFICIENCY DISORDERS

Several immunodeficiency disorders result from a combination of immune defects. Some combinations of congenital immune defects are so severe that death is a common occurrence, unless the defect can be corrected. Such conditions are classified as severe combined immune deficiency (SCID) syndromes.

PRIMARY COMBINED IMMUNODEFICIENCY

There are many primary combined immunodeficiency syndromes, which present in early childhood.[12] Specific

molecular defects have now been demonstrated for many of them. For example, defective expression of MHC class II molecules, adenosine deaminase (ADA) deficiency, and deficiency of the common γ-chain of the receptor for several interleukins (IL-2, 4, 7, 9, 15, 21) all result in a deficiency and/or functional impairment of B cells, T cells and sometimes NK cells. Deficiency of the interleukin receptor common γ-chain results from mutations of its gene on the X-chromosome and is the underlying defect of X-linked SCID.

Treatment of primary combined immunodeficiency

HSCT is the main treatment for many types of primary SCID, though enzyme replacement therapy can be effective in ADA deficiency and gene replacement therapy has been used to treat X-linked SCID. Antibody replacement with IVIg therapy and prophylaxis for opportunistic infections are also important in primary SCID.

ACQUIRED COMBINED IMMUNODEFICIENCY

Combined immune defects are a characteristic of several acquired immunodeficiency disorders.

Haemopoietic stem cell transplantation

Combined immune defects may result in severe infections in patients who have received HSCT.[13] Following transplantation, the recipient's immune system is reconstituted with donor cells. A degree of immunocompetence is passively transferred from the donor to recipient by antigen-specific lymphocytes, but as this and any residual immunocompetence of the recipient declines an immunodeficient state exists until the donor immune system is established. Consequently, both antibody-mediated and cell-mediated immunity are deficient in the first 3–4 months after transplantation and may remain deficient for a longer period of time in patients with GvHD. This combined immune defect is often compounded by neutropenia and/or the effects of corticosteroid or immunosuppressant therapy for GvHD. Defective antibody responses may persist for several years after transplantation, particularly antibody responses against polysaccharide antigens.

Critical illness

Many patients who are critically ill as a result of surgery, trauma, thermal injury or overwhelming sepsis also have acquired immune defects. These defects include abnormalities of cellular immunity, immunoglobulin deficiency and impaired neutrophil function and appear to be associated with an increased propensity to infections. Impairment of cell-mediated immune responses usually manifests as decreased T-cell proliferation and impaired delayed-type hypersensitivity responses, and probably results from a combination of factors, including the effects of anaesthetic drugs, blood transfusion, negative nitrogen balance and serum suppressor factors, including cytokines such as TNF. Phagocyte defects are mostly due to impairment of neutrophil chemotaxis by serum factors, and impaired intracellular killing. Deficiency of serum immunoglobulins also occurs, especially IgG deficiency, and may be associated with antibody deficiency. Serum leakage is a factor in patients with thermal injuries, and reduced synthesis and increased catabolism of immunoglobulins occur in many critically ill patients.

The correction of immune defects in critically ill patients has been intensely investigated, but no effective treatment regimen has been defined. General measures such as adequate nutrition, achieving a positive nitrogen balance and excision of thermally injured tissue appear helpful. Biological response modifiers, cytokine and mediator inhibitors, and IVIg therapy have all been evaluated. The number of acute infections, particularly pneumonia, can be reduced by the use of IVIg therapy, but patient survival is not increased. G-CSF levels are increased during critical illnesses and correlate with the severity of illness. Although administration of G-CSF has been shown to be safe in intensive care patients, there is no current evidence that the administration of G-CSF improves outcome and cannot be routinely recommended in the treatment of critically ill intensive care unit patients.

Asplenia and hyposplenism

The spleen is an important part of the immune system's response to infections, particularly bloodstream infections. Splenic macrophages remove opsonised microorganisms from the blood, and IgM memory B cells (also known as mantle-zone B cells) produce an early antibody response to the polysaccharide antigens of encapsulated bacteria. The risk of overwhelming postsplenectomy infection (OPSI) is around 1 in 500 per annum, with 50% mortality. OPSI is most commonly caused by encapsulated bacteria, such as *Pneumococcus, Meningococcus* and *Haemophilus influenzae*, for which vaccines are available. Other bacteria that are sometimes important include group A *Streptococcus, Capnocytophaga canimorsus* (following dog bites), *Salmonella, Enterococcus* and *Bacteroides*.

Asplenic/hyposplenic patients require education, vaccination and appropriate use of antibiotics. Pneumococcal, meningococcal and *H. influenzae* vaccines, including regular boosters, and annual influenza vaccine are recommended, preferably 14 days before removal of the spleen if performed electively, or 14 days after if not.[14] Chemoprophylaxis with antibiotics (with a penicillin, or if allergic macrolides) should be given in accordance with national guidelines; our practice is to offer them for at least 2 years post splenectomy in adults. Enrolment of patients in spleen registries, where available, can offer ongoing patient education, vaccination reminders and access to updated recommendations.

Biological immune response modulators

Anti-TNF agents such as infliximab have been associated with increased rates of bacterial infection,[15] tuberculosis and some opportunistic infection.

Antibodies targeting various B- and T-cell antigens are increasingly used for rheumatological and haematological diseases. Not unexpectedly, these agents have been increasingly associated with infectious complications. For example, the anti-CD20 antibody rituximab specifically targets B cells for its therapeutic action, but has also been associated with infectious complications such as recurrent bacterial infection, reactivation of hepatitis B, CMV and PML.

HIV and acquired immunodeficiency syndrome

Alexander A Padiglione and Steve McGloughlin

HIV/AIDS AND THE INTENSIVE CARE UNIT (ICU)

Modern antiretroviral therapy (ART) is so effective at controlling HIV replication that the mortality of patients with HIV is now similar to that for the general population. Correspondingly, the mortality risk for patients with HIV in ICU is now more closely related to their acute illness severity than to their degree of immunosuppression.[1] The proportion of HIV patients being admitted to intensive care with illnesses unrelated to their immune suppression, such as major surgery, self-poisoning and trauma, is increasing.[2]

Patients with HIV may be admitted to intensive care because of:

- *direct complications of the immune deficiency induced by HIV:* classically infections such as *Pneumocystis jiroveci* pneumonia (PJP) or cryptococcal meningitis, and occasionally tumours, especially lymphoma
- *indirect complications of HIV or its treatment not due to immune deficiency:* examples include sepsis or myocardial infarction, or drug side-effects including chemotherapy for HIV-associated cancers
- *problems unrelated to HIV infection:* such as major surgery or trauma.

The most common cause overall for admission to intensive care remains respiratory failure. Previously the predominant cause for this was PJP, but bacterial pneumonia and non-HIV-related respiratory illnesses such as chronic obstructive pulmonary disease (COPD) and asthma are increasing in prevalence. Immune reconstitution disease related to PJP, tuberculosis and other mycobacterial diseases can also cause respiratory failure in patients recently commenced on ART.

Sepsis is an important cause of admission to intensive care units amongst HIV patients, and is an independent predictor of mortality in HIV patients admitted to ICU. Bloodstream and lower respiratory tract infections are the most common. Early recognition of bacterial sepsis as a cause for an acute illness in HIV patients is vital. HIV patients in ICU also appear to be at an increased risk of developing severe nosocomial infections.[1]

HIV REPLICATION

Human immunodeficiency viruses 1 and 2 are retroviruses that exhibit tropism for cells of the immune system with subsequent immune disturbance, especially immunodeficiency. The major cell surface receptor for HIV is the CD4 molecule, but one of the chemokine receptors CCR5 or CXCR4 acts as a co-receptor. Inside the cell, the viral RNA is reverse-transcribed into DNA by a viral reverse transcriptase enzyme. This proviral DNA is integrated into the host DNA by a viral integrase enzyme. The proviral DNA remains in the nucleus until the cell is activated, when it is transcribed into RNA, which provides the template for assembly of new HIVs under the control of viral enzymes such as proteases. Budding of new virus from the cell is followed by infection of new cells and a repeat of the replication cycle.

PRIMARY HIV INFECTION

Primary HIV infection (‘seroconversion illness’) occurs in 50–75% of infected patients, typically 1–4 weeks after exposure to HIV. This infectious mononucleosis-like syndrome is characterised by fever, lymphadenopathy, headache, photophobia, fatigue and myalgia. However, mucocutaneous lesions, neurological disease and even transient immunodeficiency with secondary infections may occur.[3]

CHRONIC HIV INFECTION

The viraemia associated with primary HIV infection is controlled by cellular and antibody-mediated immune responses, which correspond with resolution of symptoms. However, HIV replication continues to take place even though most patients are asymptomatic. This results in activation of the immune system and immune dysregulation, but especially cellular immunodeficiency and in particular depletion of CD4+ T cells. These abnormalities develop at different rates in different individuals, depending on both host and viral factors. In untreated patients the median time to develop the acquired immunodeficiency syndrome

(AIDS) after acquiring HIV infection is around 9 years. However, about 5% of HIV-infected individuals have no abnormalities or evidence of CD4 loss even after 15 or more years and are referred to as long-term non-progressors.

There is a persistent immune response against the virus, but this usually slowly fails owing to CD4 cell depletion, immune dysregulation and viral mutation; viral replication increases and the other cells become infected, including macrophages and microglial cells of the nervous system.

Chronic HIV infection may cause weight loss, fevers, lymphadenopathy and diarrhoea, though such symptoms are more likely to be caused by an opportunistic infection in immunodeficient patients. Worsening HIV infection leads to a T-cell immunodeficiency syndrome manifesting in the development of opportunistic infections and tumours. These are classically PJP, Kaposi's sarcoma and T-cell lymphoma. Neurological disease may also develop, and is a consequence of HIV infection of macrophages and microglial cells in the central and peripheral nervous system. At very severe T-cell deficiency (<100 cells/mL) diseases such as cryptococcal meningitis, disseminated *Mycobacterium avium* complex (MAC) and cerebral toxoplasmosis can also occur. Globally tuberculosis (TB) is the most common consequence of HIV immunodeficiency, presenting classically as pulmonary disease at higher CD4 counts, with more unusual extrapulmonary manifestations including meningitis and miliary disease increasingly likely at lower CD4 counts.

DIAGNOSIS

A definitive diagnosis of HIV infection can be made by demonstrating anti-HIV antibodies in the patient's serum. It may take a number of weeks for HIV antibody to become positive during seroconversion. Most current testing is with combination antigen/antibody tests, which dramatically reduce any window period.[4] Laboratories have generally confirmed a positive antibody result with an HIV-specific Western blot immunoassay (though this may take time to become positive in acute HIV infection), best done on a repeat blood draw.

Most patients who develop HIV will have positive antibodies by 3 months after their exposure to the virus; after this time, absence of HIV antibodies excludes HIV infection in almost all cases.

HIV VIRAL LOAD MONITORING/GENOTYPE TESTING

Polymerase chain reaction (PCR) testing allows the quantification of viral nucleic acid in body fluids. The HIV viral load is useful in prognostication and monitoring response to treatment[5] so in stable patients it is usually tested every 3–4 months. Specific mutations in the viral RNA confer resistance to specific antiretroviral drugs. These mutations can be detected by PCR and sequencing of complementary DNA (cDNA); this genotyping is normally done at first diagnosis, or when a treatment regimen is failing, to guide subsequent therapy.[6]

IMMUNOLOGICAL MONITORING

Immunodeficiency and neurological disease caused by HIV infection usually develop gradually over years. The blood CD4+ T-cell count or percentage is the best indicator of the severity of HIV-induced immunodeficiency, and therefore of the patient's susceptibility to opportunistic infections, and may be a useful guide to starting therapy. Significant AIDS-related illnesses tend to occur at a CD4+ count of less than 200, but there is clear benefit at starting therapy in any patient with a subnormal CD4+ count.[7]

MANAGEMENT OF THE HIV-INFECTED PATIENT

The impact of combination antiretroviral therapy on the morbidity and mortality associated with HIV infection has been dramatic, and patients currently on effective treatment can expect a near-normal lifespan. Six classes of antiretroviral drugs are currently in use and function at various points in the HIV replication cycle (**Table 68.1**).

Antiretroviral drugs should not be used individually but triple combination therapy against a sensitive virus usually leads to sustained virological control without the development of resistance. Adherence to antiretroviral therapy is critical to the success of treatment. The choice of drug therapy should be based on national guidelines and individualised for patient characteristics and genotyping results.

DRUG TOXICITY

Improvements in antiretroviral therapy have seen reductions in serious adverse events due to HIV medications. Older nucleoside analogue reverse transcriptase inhibitors (NRTIs) previously associated with lipodystrophy, lactic acidosis and peripheral neuropathy and pancreatitis are now rarely used in the developed world.[9] Severe allergic reactions to abacavir have been significantly reduced by HLAB5701 testing of patients to exclude those with a predisposition.

Long-term toxicities including liver, kidney and bone disease are now more significant concerns. In some cases a combination of viral, treatment and other factors may play a synergistic or additive role in generating these toxicities; for example co-infection with hepatitis C virus is a significant risk factor for hepatotoxicity and at least some cases are probably a type of immune restoration syndrome.[10]

Table 68.1 Antiretroviral drugs used to treat human immunodeficiency virus (HIV) infection

ANTIRETROVIRAL CLASS AND EXAMPLES	MECHANISM
FUSION INHIBITORS	Block binding/fusion of the virus with the cell membrane
Enfuvirtide (T20) Maraviroc	
NUCLEOSIDE/NUCLEOTIDE ANALOGUE REVERSE TRANSCRIPTASE INHIBITORS	Substitute natural nucleoside or nucleotide analogues during HIV replication, thereby inhibiting DNA chain elongation and the effects of the reverse transcriptase enzyme
NUCLEOSIDE ANALOGUES	
Abacavir (ABV) Didanosine (ddI) Emtricitabine (FTC) Lamivudine (3TC) Stavudine (d4T) Zidovudine (AZT)	
NUCLEOTIDE ANALOGUES	
Tenofovir (TDF)	
NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS	Inhibit the reverse transcriptase enzyme preventing the formation of HIV DNA
Etravirine (ETR) Rilpivirine Efavirenz Nevirapine	
INTEGRASE INHIBITORS	Block integration of viral DNA into host DNA
Raltegravir Elvitegravir Dolutegravir	
PROTEASE INHIBITORS	Inhibit the viral protease
Atazanavir Darunavir Fosamprenavir Indinavir Lopinivir Nelfinavir Saquinavir Tipranavir Ritonavir*	

*Administered with other PIs to increase serum levels.

IMMUNE RECONSTITUTION INFLAMMATORY SYNDROME (IRIS)

IRIS is a complication related to the commencement of antiretroviral therapy and the subsequent reconstitution of the immune system. The syndrome can lead to a worsening of treated opportunistic infections or even unmask untreated infections. IRIS is more common in those patients with a history of cytomegalovirus retinitis, cryptococcal meningitis and tuberculosis, and in those with low CD4 counts. However, it can occur with virtually any opportunistic infection. ART is usually continued if mild IRIS develops. Corticosteroids, other immunosuppressive agents and even cessation of ART may be considered for the management of severe IRIS.[11–13]

HIV TREATMENT IN ICU

ART is a lifelong therapy that should be commenced in consultation with an HIV specialist. Patients already on ART should continue their therapy during an acute ICU admission, if possible. Maintenance of adequate drug delivery and absorption of ART is a particular challenge in the ICU. Options include syrup formulations, crushing tablets and the use of intravenous preparations, and drug levels of some medications can be monitored. This complex area should be managed in consultation with a pharmacist with specialist HIV knowledge.

ART also has the potential for serious drug interactions, particularly when ART includes protease inhibitors or efavirenz (metabolised via the P450 hepatic enzyme system). For example, protease inhibitors can significantly potentiate the effect of midazolam. Web-based tools are very useful (e.g. www.HIV-druginteractions.org) when prescribing antimicrobials, antiemetics and lipid-lowering drugs. The presence of renal or hepatic failure will also potentially affect the dosing of ART.

In patients who are not on ART admitted to ICU for a problem unrelated to immunosuppression, the commencement of ART can usually be delayed until after they recover. In patients admitted for an AIDS-related illness, the timing of therapy is somewhat more controversial. The potential earlier improvements in immune function need to be balanced against potential side-effects from the introduction of new drugs and increased risk of complications from immune reconstitution. Overall there is evidence in most opportunistic infections that early ART therapy is associated with improved survival.[14] Our specific practice is to initiate ART within 2–4 weeks after diagnosis of most AIDS-related infections as by this time the patient's clinical status has often stabilised, and tolerability of treatment for the infection has been established. Specific exceptions to early treatment are cryptococcal meningitis and probably TB meningitis, where early therapy is associated with a poor outcome mainly because IRIS reactions can be very severe, but also in part because drug interactions and side-effects are problematic. In these conditions, ART should not be commenced for at least 4–6 weeks.

HIV-INDUCED IMMUNODEFICIENCY

There is a strong relationship between the degree of immunodeficiency (as indicated by CD4+ count/percentage) and susceptibility to opportunistic infections. It can also guide the need for prophylactic

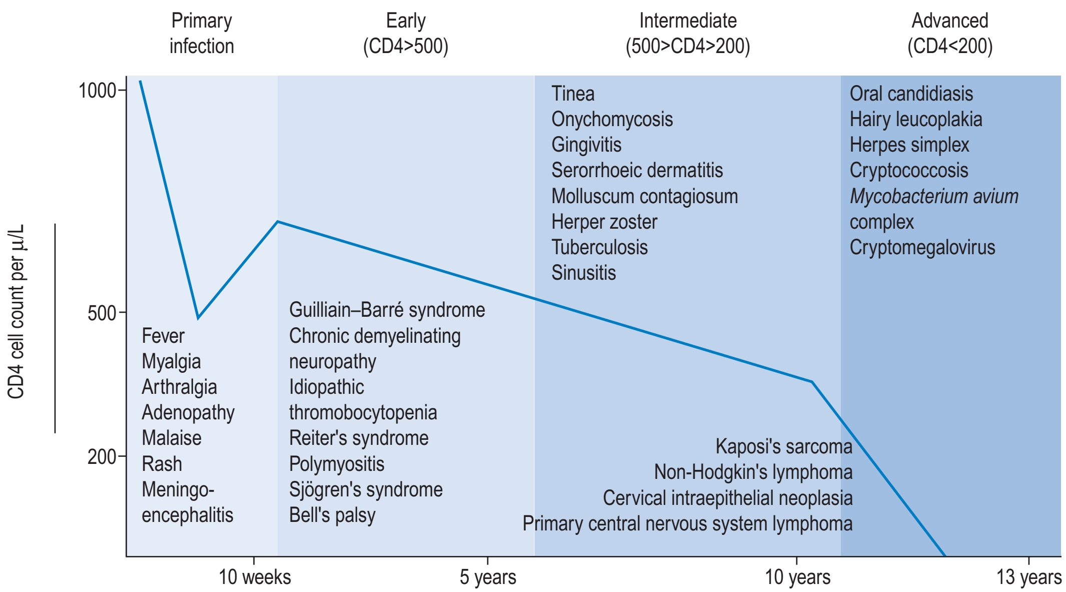

Figure 68.1 Chronological framework for understanding human immunodeficiency virus (HIV) disease and its management.

antimicrobials (**Fig. 68.1**). In addition, some patients have impaired antibody responses and phagocyte dysfunction, which predisposes them to bacterial sepsis.

MAJOR OPPORTUNISTIC INFECTIONS

PNEUMOCYSTIS JIROVECI *PNEUMONITIS*

Interstitial pneumonitis due to *Pneumocystis jiroveci* presents as subacute progressive dyspnoea, nonproductive cough and fever. Respiratory examination reveals fever and tachypnoea; however, focal signs are uncommon. The critical finding is that of hypoxia. The chest X-ray or CT scan classically demonstrates interstitial 'ground glass' infiltrates but can be normal. A definitive diagnosis is made by demonstrating *Pneumocystis* cysts in an induced sputum specimen, bronchoalveolar lavage fluid or a transbronchial biopsy.

Severe PJP is best treated with high-dose intravenous co-trimoxazole (trimethoprim-sulfamethoxazole). Many patients develop a hypersensitivity reaction to co-trimoxazole; only severe reactions necessitate changing to intravenous pentamidine. Steroid therapy must be used if the Pa_{O_2} is <70 mmHg (9.3 kPa)[15] with an Fi_{O_2} of 0.21 or if the A-a gradient is >35 mmHg. These patients are also at high risk of a pneumothorax; this needs to be considered if there is a sudden deterioration in respiratory status. Non-invasive ventilation can be effective for severe hypoxaemia; however, if mechanical ventilation is required then lung protective strategies such as low tidal volumes and plateau pressures must be implemented.

Patients with a CD4 T-cell count of <200/mL should receive PJP prophylaxis; most effective is co-trimoxazole, which has added benefit in protecting against other bacterial infections and cerebral toxoplasmosis.[16]

OESOPHAGEAL CANDIDIASIS

Candida infection of the oesophageal mucosa presents with odynophagia and dysphagia. The occurrence of such symptoms in association with oral candidiasis is usually sufficient to start treatment, most commonly with fluconazole. Endoscopy is required for a definitive diagnosis. Patients with severe immunodeficiency and prior azole exposure may have azole resistance and require intravenous amphotericin or an echinocandin.

CRYPTOCOCCAL MENINGITIS

Meningitis is the most common manifestation of infection with *Cryptococcus neoformans* in patients with AIDS. It usually presents with subacute headache and fever, but sometimes confusion or behavioural abnormalities are the predominant abnormalities. Neck stiffness is often minimal or absent, as the immune response responsible for producing this sign is minimal. Cerebrospinal fluid examination (performed after CT imaging has excluded a space-occupying lesion) may also reveal little evidence of inflammation, particularly in the most severe cases. Cryptococcal antigen is virtually always present in both serum and cerebrospinal fluid, and cultures for cryptococci are positive.[17] Intravenous amphotericin is the treatment of choice, usually given in combination with flucytosine; it must be followed by suppressive therapy with oral fluconazole until immune reconstitution is achieved with antiretroviral therapy to prevent relapses.[18]

TOXOPLASMA *ENCEPHALITIS*

Reactivation of *Toxoplasma gondii* infection most commonly presents as focal encephalitis. This may cause headaches, fever, focal neurological deficits, convulsions and even coma. Brain lesions are usually visible as multiple ring-enhancing lesions with surrounding oedema on a contrast CT scan, classically with a predilection for the basal ganglia. Serological evidence of previous *Toxoplasma* infection is present in virtually all patients, and absence of serum *Toxoplasma* antibody is strongly suggestive against the diagnosis. Treatment is oral pyrimethamine, together with either intravenous sulfadiazine or clindamycin. Hypersensitivity reactions to sulfadiazine and clindamycin are common, and an alternative drug regimen may be necessary. A brain CT scan should be repeated after 2–3 weeks of therapy, and an alternative diagnosis considered if there has been no resolution of the lesions. Cerebral lymphoma can produce very similar lesions to *Toxoplasma* encephalitis. A brain biopsy is often necessary to make the diagnosis.[19]

CYTOMEGALOVIRUS (CMV) DISEASE

CMV disease most often occurs in patients with very severe immunodeficiency (CD4 T-cell count <50/mL). The most common site for reactivation of CMV infection is the retina. CMV retinitis usually presents with unilateral blurred vision, visual field loss or ‘floaters’. Diagnosis is by fundoscopy and should be confirmed by an ophthalmologist. Treatment is usually with oral valganciclovir; intravenous ganciclovir or foscarnet are alternatives, and rarely intravitreal treatment is given. Induction is followed by suppressive therapy to prevent relapses until there is immune reconstitution following the use of ART.

CMV infection less commonly presents with disease of other organs, particularly the oesophagus, bile ducts or colon. Biopsy of affected tissue is necessary to make a definitive diagnosis. High or increasing CMV viral load in blood should prompt a search for end-organ CMV disease. CMV PCR can be used to monitor the response to therapy and detect antiviral resistance.

CRYPTOSPORIDIOSIS

Infection of the gastrointestinal tract by *Cryptosporidium parvum* causes a severe and intractable secretory diarrhoea, which is often associated with a malabsorption syndrome. It can also cause cholangitis. Diagnosis is by demonstrating *Cryptosporidium* oocysts in faeces and/or a rectal or duodenal biopsy. Antiretroviral therapy to raise the CD4 count is the best treatment.

MYCOBACTERIUM AVIUM *COMPLEX (MAC) INFECTION*

Infection with MAC is usually disseminated and affects blood leukocytes, liver, spleen and lymph nodes, and the gastrointestinal tract. Active infection often results in non-specific symptoms such as weight loss, fatigue, fevers, anaemia and diarrhoea. The diagnosis is usually made by culturing MAC from blood, but sometimes stool microscopy and culture or biopsy of affected tissues, particularly lymph nodes, are necessary. Multidrug therapy (e.g. clarithromycin, rifabutin and ethambutol) is often successful. Suppressive therapy should be continued until there is immune reconstitution following the use of ART.[20] Azithromycin prophylaxis can be considered for patients with a CD4 count less than 50.

AIDS-RELATED NEOPLASMS

Certain neoplasms with a viral pathogenesis characteristically occur in HIV-induced immunodeficiency. Kaposi’s sarcoma (KS) is an angioproliferative tumour originating from vascular endothelium, and is a complication of human herpesvirus-8 (HHV-8) infection. It usually presents as skin lesions that have a reddish-purple colour. They vary in extent from one or two small papules to numerous bulbous lesions. The gastrointestinal tract, lymph nodes and internal organs may also be involved in the severely immunosuppressed. A clinical diagnosis of KS can be confirmed by biopsy of a lesion. KS may present at any degree of immunodeficiency but occurs most often, and is more severe, in patients with moderate to severe immunodeficiency. New antimitotic agents plus antiretroviral therapy have resulted in KS essentially disappearing as a clinical problem in treated individuals.

Lymphomas can also complicate HIV-induced immunodeficiency. The great majority are B-cell lymphomas (non-Hodgkin’s), and reactivation of Epstein–Barr virus infection is implicated in the pathogenesis of most cases. Primary cerebral lymphoma or extracerebral lymphoma, which often has extranodal involvement, is common in patients with severe immunodeficiency. These lymphomas are usually high grade. Treatment consists of whole brain radiation, steroids and antiretroviral therapy.[21]

Cervical intraepithelial neoplasia and cancer are more common and aggressive in women with HIV infection, as are anal neoplasia and cancer in males.

HIV-RELATED NEUROLOGICAL DISEASE

HIV infection of macrophages and microglial cells in the nervous system often results in neurological disease by incompletely understood mechanisms. Encephalopathy, myelopathy and peripheral neuropathy are all possible. In a small number of patients, the neurological disease is more problematic than the immunodeficiency. The encephalopathy usually develops insidiously in individuals with advanced immunodeficiency and eventually results in cognitive, motor and behavioural abnormalities. Myelopathy, which is now rare, results in an ataxic spastic paraparesis.[22]

Investigation of HIV patients with space-occupying cerebral lesions requires analysis of serology, cerebrospinal fluid and neuroimaging investigations. Analysis of cerebrospinal fluid includes polymerase chain reaction (PCR) for Epstein–Barr virus (indicative of lymphoma), herpes simplex virus, CMV, varicella–zoster virus (viral encephalitis), JC virus (indicative of progressive multifocal leucoencephalopathy), toxoplasmosis and *Mycobacterium tuberculosis*.[23]

NEEDLE-STICK INJURIES AND POSTEXPOSURE PROPHYLAXIS

Patients with unrecognised HIV infection or AIDS may also be admitted to an ICU with the first manifestation of HIV disease. Known patients with HIV in the ICU may be outnumbered by undiagnosed patients with HIV; it is therefore important for all ICU staff to practice stringent infection control procedures at all times, and this will also protect them against other bloodborne viruses.

HIV transmission from needle sticks occurs at a rate of approximately 0.3%, and from mucosal exposure at a rate of approximately 0.009%. There have been no reported seroconversions after skin exposure. The major risk factors for infection after a needle-stick injury are: (1) deep injury; (2) visible blood on device; (3) needle placement in a vein or artery; and (4) a source patient with late-stage HIV/AIDS (high viral load).

Antiretroviral prophylaxis reduces transmission rates.[24] A protocol for dealing with blood and body fluid exposure should therefore be developed for every health care institution.

Severe sepsis

A Raffaele De Gaudio

Sepsis remains a common problem in critically ill patients, and is strongly related to morbidity, mortality and costs. The incidence of severe sepsis has been increasing steadily over the last three decades, in part due to the ageing of Western populations. Nearly 15% of patients in intensive care units present with severe sepsis, and two-thirds of them have septic shock. Despite intense research, only a few new therapies have been developed, and the mainstay of treatment remains non-specific advanced life support.[1–3] The failure to develop new therapies suggests that our knowledge of the pathological process of sepsis in humans is inadequate.[4]

DEFINITION

The internationally accepted definition of severe sepsis was outlined during a conference held in 2001 and 2003 and requires a specific set of physiological and laboratory indices associated with a clinical suspicion of a new onset of an infection as the source of the abnormalities[5,6] (**Box 69.1**).

Sepsis is defined as an infection associated with a systemically activated inflammation response syndrome (SIRS) and has a mortality rate of 10–15%. To further differentiate illness severity, severe sepsis is defined as sepsis with multi-organ dysfunction (mortality rate 17–20%), and septic shock is defined as severe sepsis with haemodynamic instability despite fluids and vasoactive drugs (mortality rate 43–54%) (**Fig. 69.1**). The compensatory anti-inflammatory response syndrome (CARS) following SIRS is indicative of immunosuppression that may last for a long period of time. These definitions delineate gradations of mortality risk, but they do not adequately stratify patients into homogeneous groups with respect to the underlying pathophysiology or their potential response to therapy. That is, they define concepts but do not identify patients with a single disease. To resolve this problem, a staging system (PIRO) was proposed that includes domains for **p**redisposition (premorbid illness), **i**nsult/infection (site, microbiology of infection and severity of other insults, such as trauma), **r**esponse (hypotension) and **o**rgan dysfunction (sequential organ failure assessment, SOFA).[5–7]

PATHOGENESIS

Severe sepsis represents an uncontrolled immune response (SIRS) to exposure to different types of microorganisms and microbial products (**Table 69.1**). Gram-negative bacilli (mainly *Escherichia coli*, *Klebsiella* spp. and *Pseudomonas aeruginosa*) and Gram-positive cocci (mainly staphylococci) are the pathogens most commonly associated with the development of the syndrome. Fungi, mostly *Candida albicans*, account for 17% of all cases of severe sepsis.[8]

The innate immune system describes a network of immune cells and their surface receptors designed to recognise and react to either dead tissue or pathogens. When either of these elements encounters certain lymphocytes or monocytes, it binds to pre-existing receptors and causes the activation of lymphocytes, or is ingested and then presented to cell surface receptors to activate monocytes. The expansion and activation of several immune cell lines, such as polymorphonucleocytes (PMNs) and B lymphocytes stimulated by the pro-inflammatory cytokines, then follows.

The pathophysiology of bacterial sepsis is initiated by the outer membrane components of Gram-negative organisms (lipopolysaccharide, lipid A, flagellin and peptidoglycan), Gram-positive organisms (teichoic acid, lipoteichoic acid and peptidoglycan) and fungi (mannan-proteins). These outer-membrane components and products of tissue destruction are able to bind to the CD14 receptor, a protein anchored in the outer leaflet of the surface of monocytes. Microorganism components also interact with co-receptors called Toll-like receptors (TLR), which show a degree of specificity for pathogenic microbes and tissue products (e.g. TLR2 for teichoic and lipoteichoic acid or TLR4 for lipopolysaccharide) (**Fig. 69.2**).[9–11]

The binding of TLR activates intracellular signalling pathways that trigger transcription factors, such as nuclear factor-κB, which in turn control the expression of immune response genes, resulting in the release of cytokines (**Fig. 69.3**). The appearance of a 'cytokine storm' expands beyond a restricted local microenvironment and spreads to the systemic circulation (such as through bacteraemia).[12] Immune cells secrete cytokines with inflammatory properties (TNF-α, IL-1, IL-2 and

Box 69.1 Diagnosis of sepsis

SIRS criteria
Heart rate >90 beats/min
Temperature <36.0 or >38.3°C
Blood glucose >7.7 mmol/L (in the absence of diabetes)
Respiratory rate >20/min
White cell count <4 or >12 $\times 10^9$/L
Acutely altered mental state

Sites responsible for infection
Cough/sputum/chest pain
Abdominal pain/distension/diarrhoea
Line infection
Endocarditis
Dysuria
Headache with neck stiffness
Cellulitis/wound/joint infection

Evidence of organ dysfunction
Blood pressure systolic <90/mean <65 mmHg (12/8.66 kPa) (after initial fluid challenge)
Lactate >2 mmol/L after initial fluids
INR >1.5 or a PTT >60 s
Bilirubin >34 µmol/L
Urine output <0.5 mL/kg/h for 2 h
Creatinine >177 µmol/L
Platelets <100 $\times 10^9$/L
Sp_{O_2} >90% unless O_2 given

From Daniels.[6]

IL-6) and activated leucocytes, promote leucocyte–vascular endothelium adhesion and induce endothelial damage.[7] This endothelial damage, in turn, leads to tissue factor expression and activation of the tissue-factor-dependent clotting cascade with subsequent formation of thrombin such that microaggregates of fibrin,

platelets, neutrophils and red blood cells impair capillary blood flow, thereby decreasing the delivery of oxygen and nutrients.[7,9]

Early inflammatory cytokines increase the expression of enzyme-inducible nitric oxide synthase (iNOS) in endothelial cells, and increased synthesis of the potent vasodilator nitric oxide leads to a decrease in systemic vascular resistance characteristic of septic shock. Cytokines and other inflammatory mediators induce gaps between endothelial cells by disassembling intercellular junctions, by altering the cellular cytoskeletal structure or by directly damaging the cell monolayer. The creation of these gaps can result in microvascular leaking and tissue oedema, both of which are characteristic of sepsis.[13]

IL-6 alters hepatocyte protein synthesis, inducing the synthesis of acute-phase reactants and promoting

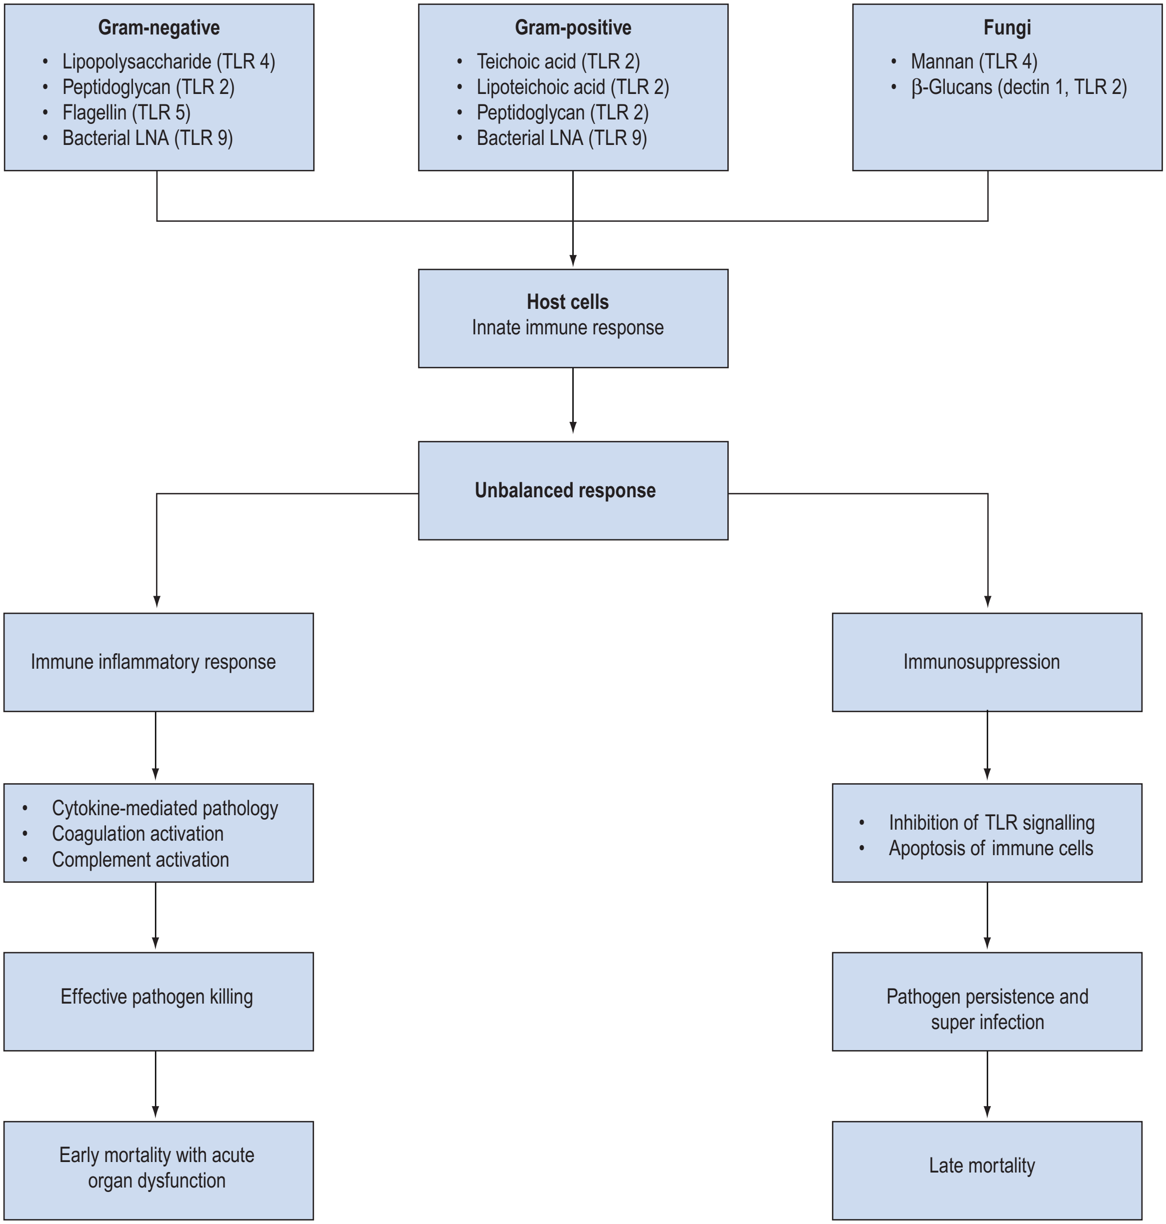

Figure 69.2 Sepsis pathogenesis and progression from effective pathogen killing to pathogen persistence and superinfection.

anaemia. The acute-phase response also results in the down-regulation of albumin production and anticoagulant proteins, such as protein C.[14]

Microcirculatory dysfunction plays a key role in the development of organ failure in severely septic patients.[15] As a result of the vicious cycle of inflammation and coagulation, cardiovascular insufficiency (due to the myocardial-depressant effect of TNF, vasodilation and capillary leaking) and multiple-organ failure occur, often leading to death.[14]

The production of anti-inflammatory cytokines (IL-4 and IL-10) during SIRS results in the expression of CARS, which is considered to be a compensatory response by the immune system in an attempt to reduce the systemic activated inflammatory immune responses responsible for tissue injury and organ failure.[16,17] This anti-inflammatory response indicates that sepsis can be associated with a state of immunosuppression that may last for extended periods of time (weeks, months and/or years) following the initial onset of SIRS.[12,16,17]

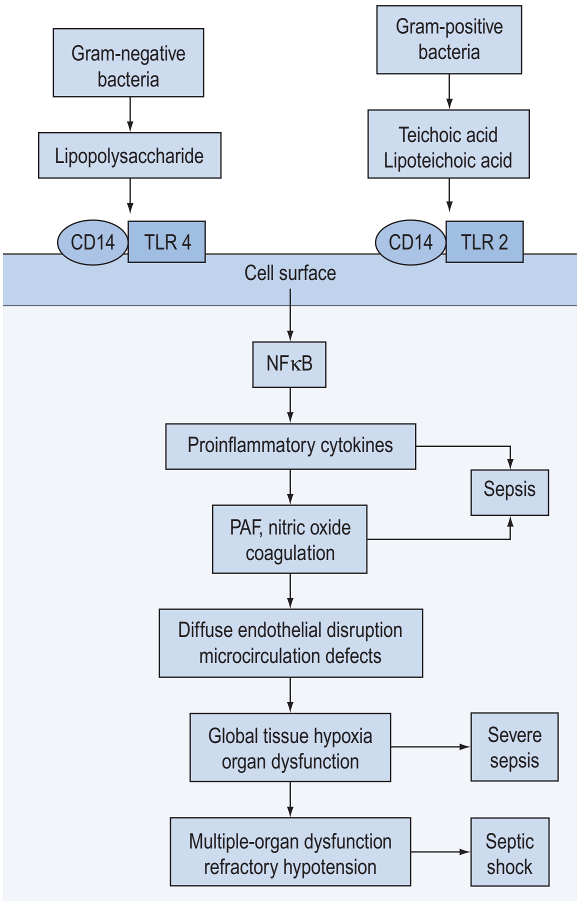

Figure 69.3 Pathogenesis of bacterial sepsis.

In many cases of sepsis, the immune system fails to eradicate the infectious pathogens, and a prolonged phase of sepsis-induced immunosuppression begins, characterised by a failure to eradicate the primary infection and by the development of secondary nosocomial infections. This immunosuppression is mediated by multiple mechanisms, including massive apoptosis of lymphocytes (see Fig. 69.2).[17]

DIAGNOSIS

The initial presentation of severe sepsis and septic shock is often non-specific and 'cryptic'. The diagnosis requires a presumed or known site of infection, evidence of SIRS and acute sepsis-associated organ dysfunction (Table 69.1).

CARDIOVASCULAR FAILURE

Adequately resuscitated patients with severe sepsis display hyperdynamic circulation with warm peripheries, low systemic vascular resistance and high cardiac output (CO). However, despite the increase in CO and normal stroke volume, many patients suffer from intrinsic myocardial dysfunction with a reduction in ejection fraction. Septic cardiomyopathy is characterised by biventricular impairment of intrinsic myocardial contractility with a subsequent reduction in left ventricular (LV) ejection fraction and LV stroke work index.[18] Bedside echocardiography is critical in the evaluation of ventricular size and function.

PULMONARY DYSFUNCTION

Detection of sepsis is facilitated by the nearly universal presence of tachypnoea and hypoxaemia. The lung can be one of the targets of the overwhelming acute systemic inflammatory response triggered in other organs. Mild, moderate or severe[19] acute respiratory distress syndrome (ARDS) can be caused by direct (pulmonary) injury, such as pneumonia, or by an indirect (extrapulmonary) insult to the lung in the case of sepsis and septic shock.[20]

SEPSIS AND ACUTE KIDNEY INJURY

According to the RIFLE (**r**isk, **i**njury, **f**ailure, **l**oss, **e**nd-stage renal disease) criteria, acute kidney injury (AKI) can be diagnosed by small changes in serum creatinine or acute reductions in urine output.[20] The development of AKI during sepsis increases patient morbidity, predicts higher mortality and has a significant effect on multiple organ functions.[21]

Until recently, it was generally believed that, like other causes of shock (hypovolaemic or cardiogenic), sepsis-induced AKI was mainly due to kidney hypoperfusion. If true, this would imply that hypoperfusion improvement and renal blood flow should be the primary targets of renoprotection in sepsis.[22]

LIVER DYSFUNCTION

The liver is a mechanical and immunological filter for portal blood and may be a major source of cytokines. An increase in aminotransferase and bilirubin levels is common, but hepatic failure is rare. Recently, subclinical liver injury has been identified in critically ill patients.

Microcirculatory changes in the liver sinusoids, neutrophil sequestration, and platelet activation and adhesion have been proposed as the main contributors to known hepatic dysfunction parameters. Cholestasis, steatosis, hepatocellular injury, impaired cellular regeneration and impaired hepatic mitochondrial respiration are factors implicated in the clinical septic hepatic dysfunction.[23]

COAGULATION ABNORMALITIES

Subclinical coagulopathy, with a mild elevation of the prothrombin or partial thromboplastin time, a

moderate reduction in platelet count or an increase in plasma fibrinogen degradation and D-dimer levels, may occur. Coagulopathy is caused by deficiencies of the coagulation system proteins antithrombin III, protein C, the tissue factor pathway and the kinin system. Simultaneous activation of coagulation by inflammatory cytokines and reduced production of anticoagulant proteins contribute to disseminated intravascular coagulation.[23]

SEPSIS-ASSOCIATED ENCEPHALOPATHY

Diffuse cerebral dysfunction is often present in sepsis and may ensue even before signs of other organ failure. It is better defined as 'sepsis-associated encephalopathy' (SAE) to stress the absence of direct infection of the central nervous system. The main sign of SAE is altered mental status. Electroencephalography is the most sensitive diagnostic test and allows the grading of the severity of cerebral dysfunction that is related to outcome. SAE is potentially reversible but always worsens the prognosis. The pathophysiology of SAE is still not completely understood, and it is most likely multifactorial. Indeed, brain dysfunction in sepsis may be related to microorganism toxin activity, the effects of inflammatory mediators, metabolic alterations and to abnormalities in cerebral circulation. Experimental studies have shown that microcirculatory dysfunction, a consequence of endothelial activation, is an early pathogenic step.[24–26]

BIOMARKERS

More than 80 biological markers of sepsis have been proposed for diagnosis and prognosis, including C-reactive protein, IL-6 and procalcitonin (PCT). PCT has emerged as the most specific biomarker for bacterial infections. A multitude of observational studies have reported on its diagnostic potential in distinct types of infections. However, PCT measurements may decrease antibiotic use without compromising clinical outcome.[27]

Several polymorphisms of genes broadly involved in inflammation, immunity and coagulation have been linked with outcome in sepsis. Since management of severe sepsis suffers from the lack of effective biomarkers and largely empirical predictions of disease progression and therapeutic responses, the availability of genetic biomarkers for predicting therapeutic responses would be very useful.[28]

TREATMENT

Timely and proper care of the patient with severe sepsis is essential. There has been considerable debate around treatment guidelines, particularly those relating to invasive management. The most widely discussed guidelines are those from the Surviving Sepsis Campaign.[6]

SURVIVING SEPSIS CAMPAIGN (SSC)

To improve the standard of care offered to patients with severe sepsis and septic shock, the Society of Critical Care Medicine, the European Intensive Care Society and the International Sepsis Forum launched the SSC with a founding statement that became known as the 'Barcelona declaration'.

The first guidelines were published in 2004, with an updated version published in 2008 and a new edition published in 2013.[29] All aspects of management of patients with severe sepsis were covered; recommendations or bundles, depending on the available level of evidence, were developed for each category. A set of the following recommendations has to be completed for all patients within the first 12 hours following the onset of severe sepsis,[29,30] which include:

- serum lactate measurements
- blood cultures obtained prior to antibiotic administration
- broad-spectrum antibiotics given within 3 hours
- source of infection identified and treated within 12 hours.

When there is hypotension and/or lactate >4 mmol/L, an initial minimum of 30 mL/kg crystalloid (or colloid equivalent) should be delivered and vasoactive drugs should be given for hypotension not responding to initial fluid resuscitation to maintain a mean arterial pressure ≥65 mmHg (8.67 kPa). In case of persistent arterial hypotension, despite volume resuscitation (septic shock) and/or initial lactate >4 mmol/L, a central venous pressure of ≥8 mmHg (1.07 kPa) should be maintained and a central venous (superior vena cava) oxygen saturation of ≥70% should be achieved.

These guidelines have been endorsed by many professional organisations worldwide and are regarded as the standard of care for the management of patients with severe sepsis.[6,29,31] However, at the moment, there is no evidence of additional beneficial effects.[6,31]

SOURCE CONTROL OF INFECTION

Adequate source control of infection is as important as appropriate antimicrobial therapy. All patients presenting with the clinical suspicion of sepsis should be evaluated for the possible presence of a focus of infection amenable to treatment by source control measures. A source of infection should be rapidly sought through integration of the clinical history, physical examination and the results of focused diagnostic tests and imaging examinations. Advances in diagnostic or interventional radiology and surgical procedures have revolutionised the management of human infections. Source control includes removal of infected foreign bodies (such as intravascular catheters and vascular draft) incision and drainage (open or percutaneous) of abscesses or fluid collections and the debridement of infected necrotic tissue; the restoration of anatomy and physiological

function is often the goal of surgical intervention. For patients with necrotising fasciitis, mortality and extent of tissue loss are directly related to the rapidity of surgical intervention.[7]

ANTIMICROBIAL THERAPY

The site of infection and causative organisms are often unknown. Broad-spectrum antimicrobial therapy must be administered empirically in these cases, guided by knowledge of the most common site of infection and the most common infecting organisms. Specimens for culture and sensitivity testing should be obtained before empirical antibiotic therapy is started. Observational studies suggest a significant reduction in mortality when antibiotics are administered within 4–8 hours of hospital admission. Current SSC recommendations consider administration of antibiotics within 3 hours of sepsis diagnosis. Despite the absence of strong evidence, antibiotic de-escalation has been recommended.[32,33] Specific antibiotic strategies may be found in Chapters 36, 54 and 70–73.

EARLY HAEMODYNAMIC RESUSCITATION (FIRST 6 HOURS)

Haemodynamic resuscitation to normal physiological parameters has been defined as early goal-directed therapy (EGDT). EGDT aims to restore the balance between oxygen supply and demand within the first 6 hours from diagnosis, leading to a significant reduction of mortality[30] and optimising the intravascular volume. A low central venous saturation ($Scv_{O_2} \leq 70\%$) coupled with an elevated lactate level suggests a mismatch between systemic oxygen delivery and oxygen consumption in the tissues. When low Scv_{O_2} is identified, therapies to increase the components of oxygen delivery are recommended to restore the balance between systemic oxygen delivery and consumption (oxygen-carrying capacity, arterial oxygen saturation and cardiac output). Despite the fact that early and vigorous fluid replacement is widely recognised as good clinical practice, EGDT has faced significant criticisms: the protocol is complex and should be implemented very early, some of the steps (use of packed red blood cells and inotropes) are not universally accepted and there is a great deal of controversy over the use of Scv_{O_2} as a surrogate of tissue hypoxia.[34] In addition, central venous pressure neither reflects intravascular volume nor predicts fluid responsiveness and has no place in the resuscitation of patients with sepsis.[31]

FLUID THERAPY

Recent advances in the pathophysiology of sepsis-related multiorgan dysfunction and on restoring tissue perfusion have provided the basis for protocols using physiology-based approaches to guide fluid therapy.[34] Initial resuscitation efforts should incorporate intravenous fluid therapy. The first goal of volume therapy of sepsis is repletion of the patient's intravascular volume deficit. The selection of crystalloid versus colloid solutions has been vigorously debated. Recently in a multicentre randomised clinical trial it was demonstrated that patients with severe sepsis assigned to fluid resuscitation with HES 130/0.4 had an increased risk of death at day 90 and were more likely to require renal replacement therapy, compared with those receiving Ringer's acetate.[35] A large volume of crystalloids is usually required, and more oedema will result. However, it is not likely that peripheral oedema carries significant clinical risk.[6] Intravenous fluid therapy should begin with 30 mL/kg of crystalloids.[29]

VASOPRESSORS

The initial goal for septic shock resuscitation includes the administration of intravenous fluid followed by vasopressor if organ perfusion cannot be maintained with fluids alone. Vasoactive agents should be administered when hypotension is persistent or mean arterial blood pressure is less than 65 mmHg (8.67 kPa). However, no evidence clearly supports the superiority of one vasopressor over another (among norepinephrine, epinephrine and vasopressin). Norepinephrine is considered as the first-line agent, followed by dobutamine or epinephrine, in patients with poor left ventricular (LV) function.[31] Dopamine has a number of theoretical disadvantages in patients with sepsis. It tends to increase heart rate and myocardial oxygen demand, and it is associated with splanchnic mucosal ischaemia.[31] Dopamine appears to increase the risk for arrhythmia if administered at high-level doses, even if there is no difference in mortality between norepinephrine and dopamine treatment.[36] The SSC recommends vasopressin infusion for refractory shock and in limited doses with the intent of raising MAP to target or decreasing norepinephrine dosage.[29] The choice of a specific vasopressor may be individualised and left to the discretion of the treating physicians.[36]

ADMINISTRATION OF ERYTHROCYTES

The patient's oxygen-carrying capacity may be augmented by the administration of packed erythrocytes to achieve a haematocrit above 30%, with a more restrictive transfusion strategy in the convalescent phase of the disease.[29,37] Although the intent of blood transfusions is to increase tissue oxygenation, this intervention may have unexpected effects. Poorly deformable transfused red blood cells may alter microvascular flow. Furthermore, the P50 of stored red cells may be as low as 6 mmHg (0.8 kPa), with the red blood cells being able to unload less than 6% of the carried oxygen; stored cells may thereby increase the Scv_{O_2} (by binding oxygen) but compound the tissue oxygen debt by decreasing oxygen unloading.[31]

ADDITIONAL GENERAL TREATMENT COMPONENTS

Additional components in the care of severe sepsis include:

- strategies to minimise oxygen demand and the fatigue of breathing (non-invasive and invasive ventilation)
- sedation with daily awakening
- adequate early enteral nutrition
- deep-vein thrombus prevention
- gastric ulcer prophylaxis
- selective antimicrobial decontamination of the gastrointestinal tract.

ADJUVANT THERAPIES

Several additional therapies initiated early after the identification of severe sepsis have been proposed to improve patient outcome. Currently, there is no consensus regarding these issues.

STEROIDS

Corticosteroid therapy has been used in various doses for more than 50 years with no clear benefit in mortality.[38] Therefore, steroid administration in severe sepsis and septic shock remains controversial. The SSC recommends the use of intravenous corticosteroids in patients with septic shock who, despite adequate fluid replacement, require vasopressor therapy to maintain blood pressure.[29] The administration of hydrocortisone in a dose of 50 mg every 6 hours or 10 mg/h[31] can be considered.

BLOOD GLUCOSE CONTROL

The prevalence of hyperglycaemia is estimated to be higher than 40% among critically ill septic patients. It is considered to be associated with increased adverse outcomes, such as poor immune response, increased cardiovascular events, thrombosis, delayed wound healing, infection and mortality. Intensive insulin therapy (IIT) is defined as the maintenance of blood glucose between 80 and 110 mg/dL (4.4 to 6.1 mmol/L). This intervention has generated a great deal of controversy. There is no evidence that IIT reduces mortality, infection rates, length of stay or the need for renal replacement therapy. Additionally there is an increased risk of severe hypoglycaemia. Currently, a target blood glucose level of 140–200 mg/dL is recommended (7.8–11.1 mmol/L).[39]

EXTRACORPOREAL BLOOD PURIFICATION TECHNIQUES[40,41]

Multiple applications of blood purification techniques in critically ill patients have made possible the evolution of management of such patients using a new therapeutic strategy called 'multiple organ support therapy'.

As in severe sepsis, the strategy is to overtake renal support and to modulate systemic inflammation, and high-volume haemofiltration (HVHF) appears to be a promising option. Although there are still no large, multicentre, randomised, controlled trials showing beneficial effects on mortality with HVHF, preliminary studies in humans and preclinical animal data support this intervention. Other extracorporeal blood purification therapies are currently available: coupled plasma filtration adsorption, polymyxin-B haemoperfusion and the use of high cut-off membranes have been proposed as adjuvant treatments for sepsis. However, it is not currently possible to determine which technique is the most effective because they have not been compared with one another. Nevertheless, an additional hybrid technique can synergistically combine HVHF and haemoadsorption in a technique called 'high adsorptive haemofiltration.'[41]

PROTECTIVE LUNG STRATEGIES, ECCO2R AND ECMO[42,43]

Low-tidal-volume ventilation (6 mL/kg with plateau pressure maintained at <30 cmH_2O) is generally well tolerated and may confer some protection against ventilator-associated lung injury. This intervention has not been associated with clinically important adverse outcomes except for hypercapnic respiratory acidosis. When lung-protective strategies are unsuccessful, various technologies, such as extracorporeal CO_2 removal (ECCO2R) and veno-venous extracorporeal membrane oxygenation (ECMO), can produce significant temporary improvement. Benefits in patient outcome have been shown with the use of these techniques in H1N1 septic patients, but this improvement does not seem to affect the outcome of other patients.[43]

ACTIVATED PROTEIN C (APC)

The use of recombinant human APC to treat severe sepsis was believed to have unique effects on the immune-coagulatory pathways; in 2001, it became the only pharmaceutical aid on the market designed specifically to treat sepsis. This intervention has generated a great deal of controversy since its introduction and in 2011, after negative preliminary results of the PROWESS-SHOCK trial, its market withdrawal was announced.[39,44]

CONCLUSIONS

The past two decades have seen a remarkable growth in our understanding of the complex interconnection of multiple biological pathways involved in the sepsis pathogenesis. However, the overall mortality rate for patients is still high. The early source control, the administration of appropriate antibiotics and the haemodynamic resuscitation remain the cornerstone of the management of patients with severe sepsis.

Nosocomial infections

James Hatcher and Rishi H-P Dhillon

Nosocomial or health-care-associated infections (HCAI) are a major problem in hospitals, affecting up to 9% of inpatients at any one time. Intensive care units (ICUs) represent 2–10% of hospital beds, but are responsible for 25% of all nosocomial bloodstream and pulmonary infections. In the European Prevalence of Infection in Intensive Care (EPIC) and EPIC II studies' snapshot of prevalence showed the infection rate in ICU was 44.8% and 51% respectively, with ICU-associated infection 20.6% in the EPIC study.[1,2] Nosocomial infection is, at least in theory, a preventable cause of morbidity and mortality (**Box 70.1**).

EPIDEMIOLOGY

The prevalence of nosocomial infection is reported as being between 3 and 12% in most institutions but varies considerably between different sites within each institution.[3] The vulnerability of the patient population, the nature of interventions and cross-infection are but three of many factors. This is seen clearly if one compares the range between ophthalmology and critical care: 0–23%.[4]

The site of infection varies with location so that, whereas the urinary tract and the chest are common throughout the hospital, within the ICU surgical wound infection, pneumonia and bloodstream infection are far more common (8–12%).

The impact of nosocomial infection is impressive. Ventilator-associated pneumonia (VAP) is common, has significant morbidity with increased length of stay, associated costs and a twofold increase in mortality.[5] It has been suggested that bloodstream infections, surgical wound infections and nosocomial pneumonia result in 14, 12 and 13 attributable extra hospital days respectively.[6] Catheter-related bloodstream infection (CR-BSI) was also associated with major morbidity although, curiously, not necessarily mortality.[7] The mortality rates directly due to these infections are hard to separate from the mortality attributed to the presenting severity of illness, which in its own right may have predisposed to infection. What is clear is that nosocomial infection is associated with increased mortality, and huge financial and resource costs.[2]

INTERACTION BETWEEN PATIENT, ORGANISM AND ENVIRONMENT

A number of factors come together to enable nosocomial infection to occur. Some may be risk factors in their own right, whereas others may simply represent an identifier of a sicker and therefore more vulnerable population (**Box 70.2**).

The host usually lives in synergistic or symbiotic tranquillity with a huge range of organisms (**Table 70.1**). Antibiotics suppress many normal organisms and allow the emergence and overgrowth of a usually insignificant organism or a resistant organism of the same type. For example, an intrinsic organism such as *Candida* will flourish in the presence of broad-spectrum antibiotics and this overgrowth may result in symptomatic or even invasive candidiasis; cephalosporin use may encourage the intrinsically resistant but quiescent enterococci to emerge as a problematic organism.

Extrinsic organisms may be introduced from the environment, from other patients, from staff or from surfaces. These may be organisms that are thriving in that environment because of local pressures (e.g. antibiotics), or from poor hygiene. Examples include *Acinetobacter baumanii* and, of course, meticillin (methicillin)-resistant *Staphylococcus aureus* (MRSA). On admission, patients will be carrying a range of organisms that have the potential to cause problems, but during their stay they are likely to acquire a new ecology from their surroundings. In a hospital that ecology may be quite hostile, with multiresistance being common.

The great debate remains as to interpretation of microbiology results in the context of a non-septic patient; is this infection or colonisation? This can be challenging to decipher and highlights the importance of reviewing the patient clinically whilst making a judgement on any positive microbiology result. No results should be acted on in isolation, and best care is often enacted through multidisciplinary efforts.

A vast range of organisms can cause nosocomial infection (**Box 70.3**). It must be emphasised that each hospital and each ICU will have its own local ecology and knowing this information is important. Regional, national and international surveys give indications of

Box 70.1 Principles of diagnosis of nosocomial infections

- Diagnosis of infection usually requires the combination of both clinical findings and the results of diagnostic tests
- Clinical diagnosis of infection from direct observation at surgery, endoscopy or other diagnostic procedure is an acceptable criterion for an infection
- It must be hospital-acquired. There must be no evidence that the infection was present or incubating at the time of hospital admission. Infection acquired in hospital, but only evident after hospital discharge, also fulfils the criteria
- Usually no specific time during or after hospitalisation is given to determine whether an infection is nosocomial or community-acquired. Each infection is examined for evidence that links it to hospitalisation (this is a matter of controversy)

Box 70.2 Risk factors for nosocomial infection

Patient
Severity of illness
Underlying diseases
Nutritional state
Immunosuppression
Open wounds
Invasive devices
Multiple procedures
Prolonged stay
Ventilation
Multiple or prolonged antibiotics
Blood transfusion
Environment
Changes in procedures or protocols
Multiple changes in staff; new staff
Poor aseptic practice – poor hand washing
Patient-to-patient – busy, crowded unit, staff shortages
The organism
Resistance
Resilience in terms of survival
Formation of slime or ability to adhere
Pathogenicity
Prevalence

general trends, but this does not supplant local knowledge.

The individual characteristics of the organism are important. These include their resilience in the local environment, the ease of transmission and the individual pathogenicity. This clearly interacts with the vulnerability of the host, as some usually innocuous organisms such as *Candida* spp. or *Serratia marcescens* will cause problems only in vulnerable hosts, whereas others such as some strains of *S. aureus, Pseudomonas aeruginosa* or *Clostridium difficile* may be intrinsically more virulent.

Box 70.3 Organisms responsible for the majority of nosocomial infections

Meticillin-resistant *Staphylococcus aureus* (MRSA)
Coagulase-negative *Staphylococcus* (CNS)
Enterococcus spp. (*E. faecalis, E. faecium*)
Pseudomonas aeruginosa
Acinetobacter baumanii
Stenotrophomonas maltophilia
Enterobacter spp.
Klebsiella spp.
Escherichia coli
Serratia marcescens
Proteus spp.
Candida spp. (*C. albicans, C. glabrata, C. krusei*)

Other organisms may be a problem in the severely immunocompromised, such as those with acquired immunodeficiency syndrome (AIDS; see Ch. 68).

Table 70.1 Common commensals that may cause infection in a vulnerable host

SITE	COMMON COMMENSAL ORGANISMS
Skin	*Staphylococcus epidermidis*, streptococci, *Corynebacterium* (diphtheroids), *Candida* spp.
Throat	*Viridans group streptococci*, diphtheroids
Mouth	*Viridans group streptococci, Moraxella catarrhalis, Actinomyces,* spirochaetes
Respiratory tract	*Viridans group streptococci, Moraxella,* diphtheroids, micrococci
Vagina	Lactobacilli, diphtheroids, streptococci, yeast
Intestines	*Bacteroides* spp., anaerobic streptococci, *Clostridium perfringens, Escherichia coli, Klebsiella* spp., *Proteus* spp., enterococci

Nosocomial infection is dynamic in that it is influenced by many environmental factors, the type of patient, type of surgery or illness, the antibiotic usage profile and many other variables. This dynamism is illustrated by the Gram-positive infections of the 1950s and 1960s giving way to the Gram-negative infections of the 1970s and, although the multiresistant Gram-positive organisms are a major anxiety currently, they are already being superseded by superresistant Gram-negative organisms such as extended-spectrum β-lactamase (ESBL)-producing *Enterobacteriaceae,* MDR *Pseudomonas aeruginosa*, *Stenotrophomonas maltophila* and *Acinetobacter baumanii*. The ease of transmission or development of resistance is a key factor in the current explosion in multiresistance.

The combination of sick patients and widespread use of potent antibiotics selects out problematic organisms and, as this epitomises intensive care practice, it is in ICU where multiresistance is common.

RESISTANT ORGANISMS

Many of the organisms that cause nosocomial infection are characterised by multiresistance. There are several mechanisms involved in resistance and in its spread. Generally speaking, there are four main mechanisms of antibiotic resistance:[8]

1. Enzymatic inactivation of drug
2. Altered drug-binding site
3. Decreased uptake of drug, either by decreased penetration or up-regulated efflux pumps
4. Bypass pathways.

Resistance is acquired in a variety of ways. Mutation of any gene occurs at a rate of one cell in 10^7 and, if this cell is then presented with antibiotics that it can survive, it will become a dominant cell, reproducing at a rate of 10^9 overnight. An example of this might be the development of AmpC β-lactamase in *Enterobacter* spp., when patients are treated with third-generation cephalosporins. A similar example is the loss of porin OprD in *P. aeruginosa* in the presence of imipenem.

Enzymes such as the β-lactamases render a large array of antibiotics useless. Class 1 β-lactamase is effective against some β-lactam-containing antibiotics but ESBLs, which incorporate enzymes such as TEM-24, will produce cross-resistance to multiple classes of antibiotics, including fluoroquinolones and aminoglycosides.[9–12]

The Ambler classification categorised all β-lactamases into four classes A–D, based upon molecular structure, and ESBLs are Class A enzymes. The major ESBL types are TEM, SHV and CTX-M, the latter being the predominant genotype globally.

AMPc enzymes are Class C, and differ chiefly in the fact they are not inhibited by clavulanate in vitro. *Enterobacter*, *Serratia* and *Citrobacter* can all produce AMPc β-lactamases. This fact is mainly of use in the diagnostic laboratory, where different markers aid in helping define potential therapeutic options. For example, β-lactamase inhibitor combinations such as co-amoxiclav and piperacillin-tazobactam may be considered in ESBL producers with mild infection, but not in AMPc producers. However, this is rarely appropriate in the ICU setting.

Resistance may be produced by a combination of mechanisms, such as in *P. aeruginosa* where the resistance is due to a combination of protein efflux systems, cephalosporinases and derepression of AmpC enzyme.

Carbapenemases were first described in the 1980s but have become prominent over the last 10 years, especially with the rise of metallo β-lactamases (MBLs). In particular the New Delhi MBL (NDM-1), which was characterised in 2008, is of growing concern as the plasmid carrying the enzyme also carries other resistance mechanisms, rendering such infections extremely drug resistant.[13]

The big problem particularly with ESBLs is that they can spread by plasmid transmission, which is very rapid. The enzyme production is encoded chromosomally within an organism, and can then be transferred between bacteria by plasmids. Transposons transfer genes between plasmids.

The phenomenon of induction is also seen. This is the process whereby the presence of an antibiotic appears to 'induce' or switch on the production of the relevant enzyme so that the organism becomes resistant. For example, staphylococcal resistance to meticillin occurs due to an altered penicillin-binding protein that has low affinity for all β-lactam agents. It is linked to a *MecA* gene, which is usually expressed only when stressed by antibiotic pressure. This gene does not develop readily and spread of meticillin resistance is by vector transmission, not de novo production of resistance[9] (**Table 70.2**).

Table 70.2 The influence of extended-spectrum β-lactamases (ESBL) on resistance in *Klebsiella*

ANTIBIOTICS	ESBL-NEGATIVE (% RESISTANT)	ESBL-POSITIVE (% RESISTANT)
Gentamicin	8	76
Amikacin	3	52
Ciprofloxacin	3	31
All the above	0	5

(Reproduced from Livermore DM, Yuan M. Antibiotic resistance and production of extended-spectrum beta-lactamases amongst *Klebsiella* spp. from intensive care units in Europe. J Antimicrob Chemother 1996;38:409–24.)

PROBLEM ORGANISMS

See Box 70.3 for organisms responsible for the majority of nosocomial infections.

These infections are likely to be associated with an increase in morbidity and mortality, primarily due to delayed recognition (no quick, reliable test currently exists that can rapidly identify such enzyme-producing strains), an association with other resistant mechanisms (ESBLs are often aminoglycoside and quinolone resistant too) and a lack of therapeutic options.[11]

An indication of their perceived importance is that, in 2010, the Infectious Diseases Society of America gave testimony before the House Committee on Energy and Commerce Subcommittee on Health on the need for antibiotic stewardship and the dire need for research and development into newer therapies. The epidemiological evidence shows that the prevalence of such infections is increasing worldwide.[12]

ESBL-PRODUCING ENTEROBACTERIACEAE

Enterobactericeae encompasses a large family of enteric, oxidase-negative, Gram-negative bacilli. In terms of nosocomial infection, *E. coli* and *Klebsiella* spp. are the most frequently seen but *Enterobacter*,

Citrobacter spp., *Serratia* spp. and *Proteus* spp. (amongst others) are also commonly implicated.

Of these *E. coli* and *Klebsiella* are particularly able to produce ESBLs, which may be defined as transferable plasmid-mediated enzymes that hydrolyse oxyimino-cephalosporins but are inhibited in vitro by clavulanate.[10]

PSEUDOMONAS

Pseudomonas spp. are versatile opportunistic pathogens common in the critically ill; they may colonise patients with chronic lung disease. *P. aeruginosa* is one of the commonest pathogens associated with hospital-acquired pneumonia. Resistance is able to develop in a range of ways and produces a very broad spectrum of resistance, making it potentially very difficult to treat and resulting in the increased popularity of combination therapy.[14] It is associated with an adverse outcome in the critically ill[15] and, like the ESBL producers, multidrug-resistant (MDR) pseudomonal strains are growing in number.[16]

STENOTROPHOMONAS MALTOPHILIA

This is an increasingly common and troublesome environmental organism. It is often resistant to β-lactam antibiotics, quinolones and to aminoglycosides. Co-trimoxazole is the only reliably effective antibiotic agent. It also produces a carbapenamase, which makes it intrinsically resistant to carbapenems. Indeed the use of carbapenems predisposes to *Stenotrophomonas* selection.

ACINETOBACTER BAUMANII

Acinetobacter baumanii is an increasing and major problem. It survives even in dry environments and, despite its name, spreads and cross-infects readily (*a cineto*: without movement). It is multiresistant and, although generally sensitive to carbapenems, it is increasingly resistant even to these agents. It becomes rapidly resistant and the profile of resistance is unpredictable but can be extremely broad, with some organisms sensitive only to colistin. [17]

It has the potential to cause significant outbreaks, and MDR strains have also been implicated in military personnel returning from Iraq and Afghanistan.[18]

COAGULASE-NEGATIVE STAPHYLOCOCCI (CoNS)

CoNS are low-virulence organisms and common skin contaminants, but are increasingly causing nosocomial infection. Their resilience may be in part due to the production of biofilm, when associated with catheter-related or bone and joint infections. Frequently meticillin resistant, they are also resistant to multiple classes of antibiotics, but are usually sensitive to glycopeptides. As glycopeptide resistance patterns alter, newer agents such as linezolid and tigecycline will have a role.

METICILLIN-RESISTANT STAPHYLOCOCCUS AUREUS *(MRSA)*

Staphylococcus aureus is a virulent pathogen causing a wide range of infections. It has a plethora of virulence factors but it is the toxins that produce most of the clinical syndromes such as invasive skin and soft tissue infections, food poisoning and necrotising pneumonia.

Meticillin resistance was first noted in the early 1960s and, although rates between countries and ICUs vary considerably, there has been an inexorable rise in its prevalence in most countries. Glycopeptides are currently commonly used to treat invasive MRSA infections but, as ever, source control is of paramount importance. Newer anti-MRSA agents include linezolid, tigecycline and daptomycin. Anti-MRSA cephalosporins have also been developed. MRSA has been a model of the failure of some infection control methods and is a well-publicised marker of quality in a health-care setting.

CLOSTRIDIUM DIFFICILE

This originally emerged as an organism that became a problem after administration of certain antibiotics, including clindamycin. It is now clear that in the critically ill it often emerges after using almost any broad-spectrum antibiotics. The organism produces toxins that can cause pseudomembranous colitis, a potentially catastrophic disease. Although it usually settles on metronidazole or vancomycin orally, recurrence is common and it can also progress to a severe colitis that necessitates radical surgery such as colectomy.[19] A newer therapeutic agent fidaxomicin shows promise against recurrent disease.[20] Surgery carries a high mortality rate, quoted at 11% for total colectomy, and very high mortality for less aggressive surgery such as hemicolectomy in the presence of toxic megacolon.[21] Almost as important is the observation of case clusters, indicating that cross-infection is important.

CANDIDA *SEPSIS*

Candida sepsis is almost always a nosocomial problem, probably endogenous in origin, and related to overgrowth secondary to antibiotic pressures. It is the fourth commonest bloodstream infection in the USA and the sixth commonest in Europe.[22]

The prevalence of species is defined by each unit, but *C. albicans* is most common. There is some evidence to suggest that the widespread use of azoles may have influenced the relative increase in *C. glabrata* and *C. krusei* species. Definitive diagnosis is by blood culture, but presumptive diagnosis is suggested by the triad of clinical infection, a high-risk patient and *Candida* at more than two sites (**Fig. 70.1**). Antifungal treatment should depend on the sensitivity of the species involved.

SITES OF INFECTION

The main sites of nosocomial infection are the respiratory system, surgical site wounds and intravenous

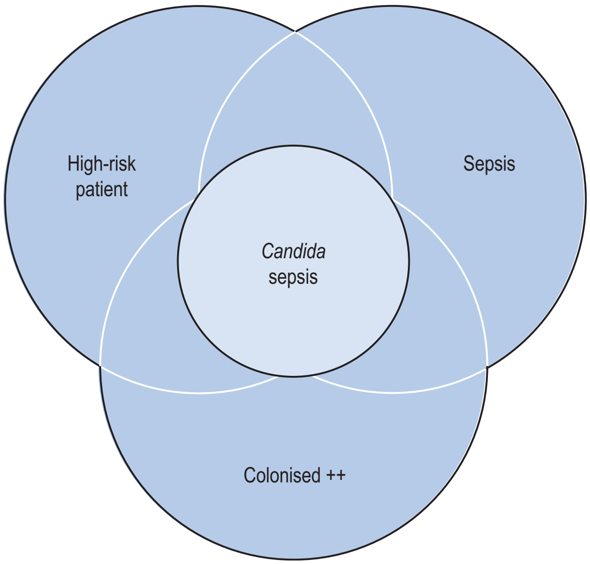

Figure 70.1 Diagnostic triad of *Candida* sepsis.

lines. Urinary tract infection appears to be relatively uncommon compared with non-critical care environments, with only 14% point prevalence in the EPIC II study compared with 64% of respiratory-related infections.

NOSOCOMIAL PNEUMONIA

Nosocomial pneumonia is a common problem in the critically ill, particularly in ventilated patients, with an incidence of 15–30%.[23–25]

AETIOLOGY

There are several possible mechanisms, including aspiration from the nasopharynx, local spread and haematogenous spread of infection. Some 45% of healthy adults aspirate in their sleep. In the sick the nasopharynx colonises rapidly with a wide range of organisms, usually Gram-negatives, and aspiration is encouraged by the unconscious state, the presence of a nasogastric tube or endotracheal intubation. Pneumonia will develop in up to 25% of colonised patients, compared with a 3% incidence in non-colonised patients. It may also be related to the colonisation of the upper gastrointestinal tract, which may in turn colonise the nasopharynx.

Factors that are likely to encourage colonisation of the pharyngeal areas with organisms include antibiotics and nasogastric tubes. Also implicated are alterations in the host defences in the pharynx, changes in the local pH, the amount of surface mucin and impairment of other local immune defence mechanisms.

Patient factors predisposing to nosocomial pneumonia include acute severity of illness, chronic illness, especially chronic lung disease, diabetes, immunosuppression, advanced age, recent surgery to thorax or abdomen, intubation, and bronchoscopy. Environmental factors include broad-spectrum and prolonged use of antibiotics, potential pathogens in the vicinity, bacterial properties such as ability to adhere to surfaces, cross-infection, 24-hour ventilator tubing changes, and foreign bodies such as nasogastric tubes. Intubated and ventilated patients have a higher rate of nosocomial infection than patients receiving non-invasive ventilation. However, this may be due to different patient populations with different underlying problems and background morbidity.[26] The role of neutralisation by H_2 antagonists and proton pump inhibitors is still debated.[27–29]

Box 70.4 Principles for the diagnosis of nosocomial pneumonia

Crackles on auscultation or dullness to percussion on physical examination of the chest and any of the following:
- New onset of purulent sputum
- Organism isolated from blood cultures
- Isolation of pathogen from specimen obtained by transtracheal aspirate, bronchial brushing or biopsy
- Chest radiography examination shows new or progressive infiltration, consolidation, cavitation or pleural effusion
- Isolation of virus or detection of virus antigen in respiratory secretions
- Diagnostic single antibody titre (IgM) or fourfold increase in paired serum samples (IgG) for pathogen
- Histopathological evidence of pneumonia

IgM=immunoglobulin M.

DIAGNOSIS

The general criteria for diagnosis are general signs of infection, clinical signs of a chest infection, purulent sputum, rising inflammatory markers, radiological evidence such as new pulmonary infiltrates, and positive cultures from sputum or blood.[23,25,30,31] These criteria are non-specific, and obtaining deep respiratory samples with quantitative analysis remains the stated gold standard method of diagnosis. This can be achieved with protected brush specimens (PBS) bronchoalveolar lavage (BAL) and protected BAL. These are difficult and time consuming and it appears that non-bronchoscopic techniques such as blind tracheal aspirates through the endotracheal tube are both practical and reasonably effective from a clinical – if not a research – viewpoint.[25,32] A recent Cochrane review showed there was no evidence that quantitative cultures (compared with qualitative analysis) reduced mortality, length of stay, time on mechanical ventilation or antibiotic change[33] (**Box 70.4**).

THE ORGANISMS

The majority of VAP is due to aerobic Gram-negative organisms such as *Klebsiella* spp., *Escherichia coli* and *Pseudomonas* spp. but early-onset VAP, between 48 hours and 5 days, may be due to community pathogens,

such as meticillin-sensitive *Staphylococcus aureus, Streptococcus pneumoniae* and *Haemophilus infiuenzae*. This has been described as early endogenous infection.

In late-onset VAP (after 5–7 days), multidrug-resistant organisms such as MRSA, *P. aeruginosa*, *Acinetobacter baumannii* and *Stenotrophomonas maltophilia* occur more commonly than in non-ICU patients.[34–36] This has been called secondary endogenous and exogenous infection.

PREVENTION

Prevention is by methods that reduce aspiration, cross-infection and contamination of respiratory devices.[31] Recommended methods include:

- hand washing
- limiting antibiotic use
- changing ventilator circuits at longer intervals – 1 week
- orotracheal, rather than nasotracheal intubation
- removing nasogastric tubes
- semirecumbent position – this reduces aspiration
- avoiding muscle relaxants
- avoiding re-intubation
- using non-invasive ventilation, where possible.

Other more controversial methods include:

- antibiotic prophylaxis after intubation
- continuous suctioning of subglottic secretions
- early enteral nutrition benefits of the colonisation of the gastrointestinal tract might be offset by problems with nasogastric tubes and nasopharyngeal colonisation
- the use of heat moisture exchangers
- closed suctioning – there is some limited evidence that it reduces VAP.

TREATMENT

The use of inappropriate or inadequate antibiotics leads to an increased mortality, so current trends are towards initial broad-spectrum antibiotics followed by reassessment and de-escalation.[37,38] As the spectrum of resistance grows it is highly likely that it will be increasingly difficult to apply this broad-spectrum empirical treatment, especially with late-onset VAP. Surveillance of current colonisation, awareness of an individual ICU's ecology and targeted treatment will replace empiric regimens. Most guidelines, including those of the Infectious Diseases Society of America, advocate the initial use of combination therapy, usually an antipseudomonal β-lactam with an aminoglycoside, especially in late-onset VAP.[25,37,39–41] The evidence is not conclusive, however, and many studies have shown good results with monotherapy.[42,43]

Duration of treatment has always been widely debated. Shorter courses are increasingly being advocated, with an 8-day course shown to be effective.[32,44] Pseudomonal or MRSA pneumonia may require longer courses, of 14 and 21 days respectively, depending on severity.[45] Linezolid appears to be a better choice than vancomycin for treatment of MRSA pneumonia.[46,47]

The attributable mortality with nosocomial pneumonia is difficult to determine because patients requiring ventilation often have a high intrinsic mortality. Rates of 30% have been quoted; pneumonia accounts for 60% of deaths from nosocomial infections. In addition, nosocomial pneumonia increases length of stay by 12–23 days.[5,48,49]

SURGICAL SITE INFECTIONS

Surgical site infections (SSI) are common and represent 20% of all nosocomial infections. The organisms involved may be those introduced at the time or from later contamination.

RISK FACTORS

- The procedure itself and the level of contamination prior to or during surgery. In clean elective surgery the incidence should be less than 10%, but where contamination may occur (e.g. bowel surgery) it may be as high as 15%. In contaminated procedures, the rate rises to around 20%, and where infection already exists it may be 40% or higher
- The surgeon's technical ability[50]
- Host factors: see Box 70.2
- The use of antibiotic prophylaxis
- Duration of stay in ICU.

PREVENTION

Clean theatres, good operating technique and thorough asepsis, both in the theatre and postoperatively, are important.

ANTIBIOTIC PROPHYLAXIS

Efficacy of antibiotic prophylaxis has clearly been demonstrated, but the unnecessary use of broad-spectrum antibiotics should be avoided. If there is no risk of infection with a clean procedure there is no place for antibiotics. If contamination is either seen or likely to occur, the use of antibiotics is to provide cover for the spillage. Effective prophylaxis requires an antibiotic:

- that covers the most likely organisms
- to be given prior to contamination (0–2 hours preoperatively)[51]
- at peak dosage at the time of contamination.

A single dose should suffice, although a second dose is recommended if the procedure extends beyond 4 hours or a significant amount of blood loss occurs. Prolonged administration:

- increases the chance of antibiotic resistance
- unnecessarily exposes the patient to adverse effects from the drugs
- encourages colonisation with resistant organisms
- ensures that if a late infection occurs it will be with an organism resistant to the prophylaxis.

Table 70.3 Surgical prophylaxis

TYPE OF SURGERY	
Abdominal wall	Insertion of mesh. Staphylococcal or streptococcal cover. In the groin, Gram-negative cover may be needed
Cardiac	Protection of valves and grafts. Staphylococci may be resistant
Vascular	Protection of grafts. Staphylococci are a major consideration. If the groin is involved, it may require Gram-negative cover
Orthopaedic	Prostheses. Staphylococci are an increasing problem
Biliary upper GI	Usually Gram-negative and anaerobic cover, with an awareness of resistant enterococci
Colorectal	Protection against faecal flora. Cephalosporins and metronidazole have been popular but predispose to developing enterococci such as *Enterococcus faecalis* or *E. faecium*, which may be multiresistant
Gynaecological	Conventionally broad-spectrum involving cephalosporins or, currently, co-amoxiclav. Metronidazole is also favoured
Urological	Protection from instrumentation of the urinary tract, Gram-negative cover. Awareness of any existing infection

GI=gastrointestinal.

In many circumstances the evidence supporting prophylaxis is minimal, and frequently the antibiotics used are inappropriate to the perceived risk. Most hospitals will have specific guidance on appropriate antibiotic prophylaxis tailored to the procedure, taking into account local microbial resistance data. With grafts, mesh or prostheses the morbidity from infection is so great as to justify using prophylaxis even if the evidence is marginal (**Table 70.3**).

LINE SEPSIS

The use of intravascular devices in hospital practice is ubiquitous. There is both a significant morbidity, resulting in prolongation of hospital stay, and an attributable mortality due to infection associated with their use.[52–54] The catheter type influences the rate of infection. A systematic review[55] showed the following rates per 1000 catheter days:

- peripheral intravenous catheters – 0.5 (95% CI 0.2–0.7)
- non-cuffed central venous catheters
  - non-medicated and nontunneled – 2.7 (95% CI 2.6–2.9)
  - non-medicated and tunneled – 1.7 (95% CI 1.2–2.3)
- cuffed and tunnelled central venous catheters – 1.6 (95% CI 1.5–1.7)
- arterial catheters for haemodynamic monitoring – 1.7 (95% CI 1.2–2.3)
- pulmonary artery catheters – 3.7 (95% CI 2.4–5.0)
- peripherally inserted central catheters – 1.1 (95% CI 0.9–1.3)
- peripherally inserted midline catheters – 0.2 (0.0–0.5).

Box 70.5 Risk factors for catheter infection

Host risk factors

Site: subclavian is a lower risk than internal jugular and femoral

Catheter material: antibacterial catheters may reduce infection; antiseptic catheters reduce colonisation

Number of lumens: multilumen catheters increase the infection risk[30]

Number of administrations through the lines

Dressing type: frequency of changes

Skin preparation

Experience of technique of personnel

Occurrence of bacteraemia

Tunnelling: often used for long-term access but the data are contentious[31]

Central venous catheters common in the ICU have a higher rate of infection, but it is important to note that all indwelling lines pose an infection risk. Many other factors influence development of infection, such as conditions of insertion, catheter care and duration of catheter. Peripheral catheters should be changed every 72 hours; however, there is no indication for routine CVC line changing based on catheter days (**Box 70.5**).

CENTRAL VENOUS CATHETERS

Colonisation of catheters is common and it is likely that this is a precursor of infection. Colonisation rates are in the order of 5–40%, determined in part by the risk factors involved (see below). Infection rates are approximately 10% of the colonised catheters.[56]

DEFINITIONS

1. *Colonised catheter:* growth of >15 colony-forming units (semiquantitative) or 10^3 (quantitative) from a proximal or distal catheter segment in the absence of accompanying clinical symptoms and signs.
2. *CR-BSI:* isolation of the same organism from the catheter segment (see above) as from a peripheral blood culture in a patient with signs of infection and in the absence of another source. In the absence of laboratory corroboration of infection, effervescence of infection after removal of the catheter may be taken as circumstantial evidence.

Extrinsic mechanisms associated with developing catheter sepsis include infection from the skin and insertion site, contamination from the hub and then internally spread, and contamination of drugs or fluids administered through the catheter. Bacteraemia seeding to the catheter is an intrinsic mechanism.

THE ORGANISMS

The organisms involved in catheter sepsis are influenced predominantly by the patient's endogenous flora. There is a 25% incidence of CoNS, which are increasingly recognised as pathogens due to their ability to form biofilms on prosthetic material. A biofilm is a three-dimensional matrix of extracellular polymeric material (slime) that allows bacteria to live in communities. These are important owing to the increased resistance to antimicrobials and strong adherence to prosthetic material.[57] *Staphylococcus aureus* (meticillin susceptible and resistant) and *Candida* spp. can cause significant bacteraemia, and seeding to other organs such as the eyes and heart valves must be ruled out. Gram-negative pathogens predominate in patients with haematological malignancies, and *Pseudomonas* is frequent in burns patients.

TREATMENT OF CATHETER INFECTION

The most important aspect of treatment is a high index of suspicion that leads to removal of the device if infection is present either locally or systemically.[53] Antibiotics after line removal are recommended. Duration of treatment varies: 5–7 days for CoNS, and 10–14 days for *S. aureus*, Gram-negative organisms and *Candida* spp.[53] If bacteraemia is present it is best to avoid replacing the central venous catheter if possible for a few days. In situations where it is uncertain whether the line is implicated in infection, some advocate replacing a new line over a wire. If the removed catheter is subsequently shown to be infected then it must be removed.

Due to biofilm production, all lines should be considered for removal, but some long-term lines such as Hickman catheters may not be appropriate to remove, and salvage therapy instigated instead. This high-risk strategy is not routinely recommended, especially if the organism is highly virulent, but 14 days' antibiotics via the line would be minimum.

PREVENTION

Important issues include adequate hand washing, adequate skin disinfection, insertion under aseptic conditions, intravenous team to insert and manage lines, anchoring of lines to prevent excessive movement, closed systems with limited interruptions to the lines, application of sterile dressings to the insertion site, and daily inspection of catheter site. Replacement of intravenous administration sets at 72 hours is optimal. Stopcocks may be essential, but are portals of infection. Local antiseptics are advocated for site care, but there is little difference between gauze and transparent dressings, although efforts to reduce local humidity at the site may be important.[58–60]

Techniques of unproven benefit include antiseptic cream at insertion site, routine changes of dressings at frequent intervals, antibiotic lock therapy, occlusive antimicrobial dressings, in-line filters, tunnelling of central venous catheters, and routine flushing of long-term central venous catheters.

METHODS OF INFECTION CONTROL

Each hospital has an infection control team that can employ techniques to reduce infection (**Box 70.6**). Prevention of nosocomial infection, thus reducing length of stay, will decrease antibiotic utilisation and therefore generation of multidrug resistance.

The most important aspects of preventing nosocomial infection and facilitating infection control are simple hygiene, such as hand washing, and being aware that the problem exists. There are several ways in which the issue of nosocomial infection can be addressed. These include surveillance, screening, isolation and strategic planning.[61]

SURVEILLANCE AND SCREENING

Routine culture surveillance of both patients and environment provides information on the organisms currently prevalent, and is a useful tool in guiding management when infection occurs. Molecular typing of specific pathogens allows identification of cross-infection, and gives the clinician the ability to track the organism during an outbreak.

Screening of patients allows identification of multidrug resistance organisms and therefore barrier precautions to be implemented. MRSA, VRE and *Acinetobacter baumanii* are organisms targeted during screening.

ISOLATION

Although physical barriers undoubtedly reduce cross-contamination, isolation may be hazardous as it often indicates lower-intensity care. The relative risks need to be addressed.

STRATEGIC PLANNING

There are two elements. One is enforcing hygienic practice, which is simple, cheap and very effective. The other is looking towards means of reducing both

Box 70.6 Roles of infection control teams

- Surveillance and investigation of infection outbreaks
- Education of staff
- Review of antibiotic utilisation
- Review of antibiotic resistance patterns
- Review of infection control procedures and policies

nosocomial infection and the emergence of resistance by good antimicrobial stewardship.

On an individual basis the approach to management must change. In the past, empirical treatment on the basis of likely organisms led to the use of very-broad-spectrum antibiotics. Narrow-spectrum targeted treatment will cease to be an option and will become a necessity. Prolonged broad-spectrum antibiotic management aimed at dealing with any eventuality will be replaced by short-duration specific and effective regimens.

SELECTIVE DECONTAMINATION OF THE DIGESTIVE TRACT

SDD is based on the idea that elimination of colonising organisms in the gut will reduce nosocomial infection as the majority of infections arise from endogenous flora. Administration of oral non-absorbable antibiotics, such as polymyxin and nystatin, are applied to the oropharynx and stomach in conjunction with a parenteral cephalosporin. The uptake of this technique has been limited owing to concerns over antibiotic resistance generation, but it is associated with a higher survival at day 28, lower incidence of bacteraemia, and reduced VAP.[34,62–64] It is likely to be most effective in ICUs with low levels of antibiotic resistance.[65]

Severe soft-tissue infections

Ilker Uçkay, Hugo Sax, Pierre Hoffmeyer, Daniel Lew and Didier Pittet

PATHOGENESIS

The skin is the largest organ and acts as an excellent barrier against infection. It consists of the epidermis and dermis and resides on fibrous connective tissue, the superficial and deep fasciae. The fascial cleft, with nerves, arteries, veins, lymphatic and adipose tissue, lies between these fascial planes. Microorganisms cause skin and soft-tissue infections if there is a break in the skin because of traumatic lesion or maceration; soft tissues are ischaemic; particularly virulent bacteria such as community-acquired meticillin-resistant *Staphylococcus aureus* (CA-MRSA),[1] surgical site infections,[2] or in severely immune-compromised patients.[2–4] Skin lesions can on occasion be manifestations of systemic infection; examples are bacteraemia due to meningococci, staphylococci, and endocarditis. This issue is not specifically addressed here.

MICROBIOLOGY

Normal human skin flora includes coagulase-negative staphylococci, *Corynebacterium* spp., *Micrococcus* spp. and *S. aureus* for roughly 20–30% of all humans. Colonisation by Gram-negative bacteria usually occurs in hospital patients or transiently in arid areas by *Acinetobacter* spp. However, substantial skin infections due to human skin flora are exceptions. The classical pathogens of deep-layer soft-tissue infections are beta-haemolytic streptococci, notably *Staphylococcus pyogenes*, and *S. aureus* in iatrogenic cases. Of note, the virulent *S. pyogenes* can equally cause nosocomial infections (including necrotising fasciitis[5]) following needle stick injury from patient to surgeon[6] or from patient to nurse,[7] or cause invasive disease among elderly home patients.[8] This microbiology of severe soft-tissue infections has not changed significantly over recent decades[9] with three main exceptional trends: CA-MRSA is an emerging severe tissue infection in certain parts of the world,[1,10] there is awareness of severe *Acinetobacter* infections following war trauma and natural disasters in arid regions of northern Africa and the Middle East,[11,12] and earthquakes (with associated tsunamis) all over the world have highlighted the potential of atypical microorganisms (mycobacteria, *Scedosporium* spp., *Aeromonas* spp., *Vibrio* spp., *Pseudomonas* spp.) as causes of soft-tissue infections.[11,13]

DIAGNOSIS

Diagnosis of skin and soft-tissue infections is essentially clinical. Chemistry confirms inflammation and measures its severity for the follow-up of patients. Microbiological confirmation (blood cultures, abscesses) is necessary for a targeted antibiotic therapy by avoiding empirical broad-spectrum antimicrobial therapy. Growth of microorganisms per se in superficial or deep necrotic swabs is not evidence of infection, as the differential diagnoses of skin and soft-tissue infections (ischaemia, necrosis, allergy, pyoderma gangrenosum) may equally interrupt the cutaneous barrier with consequent colonisation with all kind of bacteria. Additionally, a positive skin carriage for MRSA correlates only poorly with the pathogen of subsequent cutaneous infection[14] and patients who were pretreated with antibiotics before hospital admission may reveal negative results. Serology is of inferior importance. Practically, only the serum antistreptolysin-O antibody titres may diagnose infection by beta-haemolytic streptococci of groups A, C and G.[15] Histology may help to confirm clinical suspicion, especially for necrotising fasciitis,[16] whereas radiology detects abscesses or confirms fasciitis,[17] guiding the surgeon for appropriate debridement.

CLASSIFICATION

The classification of skin and soft-tissue infections based upon pathogenesis or microbiology can be confusing, because almost every pathogen can reveal every clinical picture. For example, *S. pyogenes* can be responsible for erysipelas infecting only superficial skin layers, or can spread into deeper tissues to cause fasciitis with or without associated myositis. The exact reason why some infections remain superficial and others turn bacteraemic or penetrate to deeper structures is largely unknown (besides surgical site or trauma-related infections). Many clinicians' experience is that *S. aureus* tends to form localised abscesses or evolves to bacteraemic diseases without local spread,

whereas streptococci, and especially *S. pyogenes*, tend to spread within collagenous tissue and fascias owing specialised virulence factors such as hyaluronidase. However, this distinction can be arbitrary. In the following text, we will summarise some key elements of possible clinical presentations.

CLINICAL PRESENTATIONS

SUPERFICIAL SKIN INFECTIONS

Most of this group will never progress to a severe sepsis necessitating intensive care. Impetigo, more common in children, is a superficial skin infection characterised by yellow pigmentation and caused by *S. aureus*, or *S. pyogenes*. Mild infections are managed with topical antibiotics; more severe ones need a first-generation cephalosporin or a penicillinase-resistant penicillin.[18] Resistance in streptococci and staphylococci might prohibit macrolides or clindamycin, which are alternatives in penicillin-allergic patients. For CA-MRSA, oral co-trimoxazole or clindamycin is the usual choice.[1,10] Folliculitis with subsequent abscesses arises spontaneously in hair follicles and apocrine glands. Classically, *S. aureus* is the causative organism. When confluent, folliculitis can evolve to furunculosis and may need surgical drainage. Topical or systemic antibiotics may be required to prevent recurrence in selected cases. Repeated folliculitis raises the possibility of diabetes mellitus or chronic granulomatous disease, an inherited immunodeficiency syndrome based on granulocyte malfunction.[19]

Erysipelas is the most severe form of a skin infection, which can lead to bacteraemia in roughly 2% of cases. This dermal infection is largely caused by group beta-haemolytic streptococci and by *S. aureus*.[3,4] The prominent lymphatic blockade results in a painful bright red patch with a raised sharp border, which clearly demarcates infection from surrounding skin. Predisposing conditions include interdigital mycoses, foot abrasions, chronic ulcers, lymphoedema, venous stasis, and diabetes. (Amino) penicillins, cephalosporins or amoxicillin/clavulanate are the drugs of choice. Often clinicians empirically administer antibiotic agents with a broader spectrum, especially for pretreated patients or those in intensive care. However, cases not covered by cephalosporins or amoxicillin/clavulanate are rare (with the exceptions of CA-MRSA). It is rather a hallmark of clinical disease that severe erysipelas does not respond immediately to (correct) antibiotic administration. Often, it takes courage to wait several days and to retain, giving escalation of anti-infective therapy to a broader spectrum. When there is a poor response, collections and abscesses amenable for drainage need to be searched for. In patients with lymphoedema and recurrent erysipelas, secondary prophylactic therapy with (benzathyl)-penicillin may help to prevent further episodes.[18]

DEEP SKIN AND SOFT-TISSUE INFECTIONS

Cellulitis[4,5,18] is an acute spreading infection with tissue necrosis and eventual collections, but does not involve the fascias. There is less lymphatic involvement so the borders of the infection are often not well defined and differentiation between cellulitis and erysipelas is sometimes difficult. Fever, malaise and rigors are common. Cellulitis is most commonly due to streptococci, but other Gram-positive and -negative organisms can also cause this condition.[4,18] External facial cellulitis may involve the venous system draining into the sinus venosus and thus lead to thrombosis. Periocular cellulitis is a medical emergency. Clinical signs for the latter include visual disturbance because of optic nerve involvement. The orbital entity includes a wider range of bacteria: *S. pneumoniae, Haemophilus influenzae, Moraxella catarrhalis, S. aureus*, *S. pyogenes* and anaerobes. Another severe form of cellulitis with hemorrhagic bullous lesions can be caused by marine bacteria such as *Vibrio* spp., mostly in cases with a history of contact with seawater.[11]

TOXIN DISEASE

S. aureus and streptococci may cause sepsis not only by local inflammatory damage, but also by superantigens and toxin production. These cases are called staphylococcal or streptococcal '(toxin) shock syndromes' and are marked with signs of septic shock with absence of locally spreading infection. Sometimes, a fine macular rash on the patient's skin indicates the toxin. Regarding staphylococcal shock syndrome, a forgotten female vaginal absorption tissue (tampon), has been identified as a possible origin.[13]

NECROTISING FASCIITIS AND MYOSITIS

Necrotising fasciitis and myositis are the most feared soft-tissue infections that can affect even the healthiest young individual with very rapid onset and rapid progression to death.[18,20,21] Fatality rates range between 20–30% all over the world,[22–24] although a lower incidence of 17% is also reported.[25,26] Involvement of genitalia is called Fournier's gangrene.[24] Unsurprisingly, many papers have been published on necrotising fasciitis (e.g. a PubMed search at the end of 2011 reveals 2848 citations for 'necrotising fasciitis'). Patients with immune suppression such as diabetes mellitus appear to be particularly at risk.[27] Formally, two types are described, depending on causative organisms.[20] Type I comprises mixed infections (in immune-suppressed individuals). Type II infections are by definition caused by *S. pyogenes* and are very rapidly progressive (in otherwise healthy patients). However, this distinction is academic. There is no difference in morbidity, mortality or initial management between the two types of infection.

Figure 71.1 Necrosis on the calf due to progressive underlying necrotising fasciitis.

Clinically, necrotising fasciitis begins as cellulitis or erysipelas that fails to improve on antibiotics and quickly spreads along fascial planes, accompanied by destructive bacterial enzymes and toxins that cause necrosis and liquefaction of the surrounding tissue.[27] From the outside, there is often a disproportion between the character of the visible injury or erythema and the intensity of pain. Fever and crepitus on admission may be rare.[28] Microthrombi[16] and impaired blood supply lead to deep gangrene. Spontaneous drainage of debris and pus does not occur. Bullae may form and late lesions may resemble deep burns (**Fig. 71.1**) that may become pain-free because of nerve fibre necrosis. In untreated cases, there is a rapid spread to surrounding tissues and bacteraemia, with onset of multiorgan failure and death.

Often, the fasciitis also involves musculature. Thus, anatomically speaking, most necrotising fasciitis cases are musculofascitiis, or fasciomyositis, although separate myositis cases may occur. Increases in serum creatine phosphokinase may suggest muscle involvement. The bacterial infection of muscles by *Clostridium perfringens* or *C. septicum* is called 'gas gangrene', as crepitus may occur (**Fig. 71.2**), but is rare nowadays. Predisposing causes for gas gangrene are contaminated anaerobic wounds (e.g. in war or septic abortions).

TREATMENT

Superficial skin infections, erysipelas and cellulitis are treated by antibiotics alone, whereas abscesses, fasciitis, or myositis require a combined surgical and medical treatment (**Table 71.1**). Only in selected cases of deep severe soft-tissue infections and absence of sepsis or collections can a purely conservative medical approach lead to success.[22,29]

SURGICAL TREATMENT

A surgeon experienced in the treatment of necrotising fasciitis should be involved as early as possible, even if there is no immediate surgery performed. The decision for surgical intervention and timing should be taken together. Often, experienced surgeons may delay and avoid intervention if the patient is stable and the clinical diagnosis is unclear. When the decision for intervention is made, an extensive surgical removal of damaged tissues is essential.[30,31] During intervention, the surgeons may see greyish necrotic fascia, a lack of resistance of normally adherent muscular fascia to blunt finger dissection, lack of bleeding from the fascia or dishwater pus. All involved tissue that can easily be elevated off the fascia with gentle pressure or finger spreading is debrided[27] (**Fig. 71.3**). Numerous studies have shown the importance of the extent of the first debridement.[27] A planned second look at 24-hour intervals to debride necrotic tissue is usual. In extreme cases, if only the extremities are involved, amputation may be life-saving.

When infection is stopped and all necrotic tissues debrided, wound closure may become a major problem. Besides healing by secondary intention or meshing, musculocutaneous flaps or vacuum-assisted closure therapy[32] are modern approaches of reconstructive surgery.

Figure 71.2 Gaseous cellulitis in a standard X-ray.

Table 71.1 Pathogens and presumptive antibiotic therapy in severe soft-tissue infections*

DISEASE	MAIN PATHOGENS	ANTIBIOTIC CHOICE*	REMARKS**
Erysipelas	Beta-haemolytic streptococci (rarely, *S. aureus*)	Penicillin G or amoxicillin/clavulanate or first-generation cephalosporin	
Cellulitis	Beta-haemolytic streptococci, *S. aureus*; rarely, various other organisms	First-generation cephalosporin, amoxicillin/clavulanate clindamycin (for severe penicillin allergy)	Clindamycin resistance in *S. pyogenes* and *S. aureus* exists. Vancomycin when high suspicion of MRSA
Necrotising fasciitis	Type I: mixed. Anaerobic species together, streptococci and Enterobacteriaceae Type II: *S. pyogenes*	Empirically, high-dose amoxicillin/clavulanate IV, plus clindamycin IV	Surgical debridement essential Add vancomycin if MRSA likely Immunoglobulin in severe life-threatening sepsis
Myositis	*S. aureus*, beta-haemolytic streptococci, rarely *C. perfringens*	Empirically, high-dose amoxicillin/clavulanate IV, plus clindamycin IV	Surgical debridement essential Add vancomycin if MRSA likely Immunoglobulin in severe life-threatening sepsis

*Once causative pathogens have been identified, antibiotic choice can be modified and its spectrum narrowed.
**Be aware of local endemicity of community- or hospital-acquired meticillin-resistant *S. aureus* (MRSA). Co-trimoxazole or clindamycin are the choice in most community-acquired low-grade infections, for all other cases vancomycin.

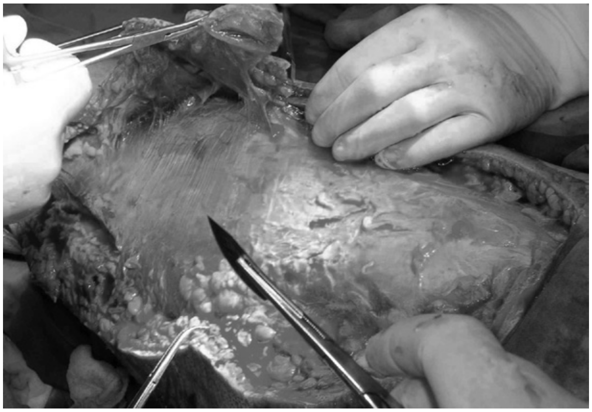

Figure 71.3 Debridement of fascia. All infected tissue is elevated off.

MEDICAL TREATMENT

Besides supportive intensive care, which is discussed in other chapters, appropriate antimicrobial agents are central to medical management of necrotising fasciitis, myositis, cellulitis and erysipelas. The role of immunoglobulins or hyperbaric oxygen is supportive at best.

Initial empirical antibiotic therapy often includes a carbapenem or other broad-spectrum antibiotic (plus vancomycin in many cases) while awaiting culture results. This broad-spectrum choice is due to fear of a potentially lethal evolution rather than supported by microbiological data. Indeed, beta-haemolytic streptococci and *C. perfringens* are susceptible to penicillin. *S. aureus* is usually susceptible to first- and second-generation cephalosporins or amoxicillin/clavulanate. Hence, even in polymicrobial infection, these most damaging pathogens are still largely covered by cephalosporins or amoxicillin/clavulanate. Besides eventual allergies or nosocomial infection, there is no need to cover larger. According to the published literature[5,20] and personal experience, almost all retrospective assessment of community-acquired fasciitis cases confirms that initial broad-spectrum coverage was excessive and antibiotic therapy could have been restricted to penicillins.

The duration of antibiotic therapy for patients with septic shock depends on the presence of secondary haematogenous seeding and the patient's evolution.[33] As for non-bacteraemic severe skin and soft-tissue infections, there is no convincing evidence regarding the ideal duration of antibiotic therapy. Often, the clinical evolution, the presence of undrained microabscesses and the experience of the physician should decide the duration, which might nevertheless be excessive in many cases. For erysipelas, the authors of this chapter performed a single-centre retrospective study highlighting that, after case-mix adjustment, less than 12 days of treatment yielded the same outcome as a prolonged treatment for more than 21 days.[14] Another randomised study among 121 cellulitis patients showed the clinical equivalence of a 5-day levofloxacin therapy compared with 10 days of levofloxacin.[34]

For (myo)fasciitis, and shock syndromes due to superantigens and toxin production, clindamycin 600 mg intravenously 6-hourly (or 900 mg t.i.d) is often added for 3–5 days,[35] even if the pathogen is clindamycin-resistant. The rationale lies in the inhibition of toxin production.[35] This is mostly supported by in vitro data. In vivo, to the best of our knowledge, only one observational study investigated the clinical benefit

of supplementary clindamycin and found a positive result with a large confidence interval (univariate analysis, non-adjusted odds ratio 4.7, 95%CI 1.0–25).[36] Likewise, limiting the duration of clindamycin administration to 3–5 days or the absence of other superantigen-blocking agents relies on expert opinion.

Intravenous immunoglobulins are regularly debated as supportive therapy to antimicrobial agents. Today, their rationale lies in the activation of complement, promotion of antibody-dependent cytotoxicity, reduction of interleukin-6 and TNF-alpha production,[36] and in the inhibition of superantigens.[37] Their clinical evidence stems from several in vitro and at least five in vivo articles published in one scientific journal[29,35–39] by the same group of researchers. This group published the best available evidence in 2003 with a European randomised double-blind placebo-controlled trial among patients with toxic shock syndrome (not all patients had necrotising fasciitis). The primary end-point was mortality after 28 days. There was a non-significant trend to lower mortality in the group treated with immunoglobulins compared with placebo (2/10 vs 4/11).[39] Adjustment for case-mix could not be performed owing to the small study population of only 21 patients. The authors concluded from their dataset that immunoglobulins are very probably beneficial. The recommended doses of immunoglobulins vary according to different authors and time. The literature suggests either single doses of 2 g/kg[36] or a 3-day course beginning with 1 g/kg the first day, followed by 0.5 g/kg the two other days.[39] Taken together, these studies provide some promise, however, additional studies are urgently needed before a strong recommendation can be made regarding use of expensive and potentially harmful immunoglobulins in necrotising fasciitis. Of note, different formulations of pooled polyspecific immunoglobulins seem to have different potency against streptococcal and staphylococcal superantigens,[38] of which the clinical significance remains unclear.

Hyperbaric oxygen therapy is costly, labour-intensive, and not without risk, but can be delivered safely also to critically ill patients.[40] The rationale for soft-tissue infections is based on logical concepts (e.g. for anaerobic gas gangrene) and on personal experience. To the best of our knowledge, no randomised trials and no case–control studies exist. Nevertheless, good outcomes in individual cases allow the Center for Medicare and Medicaid Services in the USA to reimburse its use in necrotising fasciitis and gas gangrene. The situation is similar in many European countries. Hyperbaric oxygen therapy harbours today a grade C evidence level and a grade IIb class of recommendation.[40] Its importance remains behind surgical and antibiotic treatment. Importantly, hyperbaric oxygen therapy should never delay surgical intervention, including for gas gangrene.[27]

FUTURE ASPECTS

The future will hopefully show strong prospective-randomised data about the optimal management of severe soft-tissue infections. Due to their low incidence and the large and heterogeneous case-mix of these infections, multidisciplinary and multicentre trials are needed regarding all aspects of care – from the post-debridement surgical approach to the role and dosing of clindamycin and immunoglobulins in the early management of these infections. Finally, the benefit of the available 26-valent vaccine against *S. pyogenes* and related invasive infections has to be better shown, and potentially implemented on a large scale.[23]

Principles of antibiotic use

Jeffrey Lipman

The intensive care unit is always the area of any hospital associated with the greatest use of antibiotics. Much of this high usage is unavoidable, but the clinician working in the ICU must realise that there is an essential consequence of this use. Antibiotic use, which should eliminate susceptible organisms, promotes (over)growth of other non-susceptible organisms, especially fungi. As far as bacteria are concerned, antibiotics confer enormous selective advantage to resistant strains, and therefore these strains will congregate where their advantage is greatest – in the ICU. Resistance (and fungal overgrowth) is a direct consequence of usage, and every course of inappropriate antibiotics should be avoided to help reduce the burden of resistance.

Antibiotic stewardship[1,2] has been suggested as a new strategy to help limit resistance. This involves selecting an appropriate drug and optimising its dose and duration to cure an infection while minimising toxicity and conditions for selection of resistant bacterial strains. Inadequate doses of even the 'correct' antibiotic may lead to survival of initially susceptible organisms.[3,4] For the optimal use of antibiotics not only should antibiotic pharmacokinetics be understood but also there should be clear and rational principles on which each specific antibiotic prescription in the ICU is based. In addition, it is probably better to have portions of the ICU population receive different classes of antibiotics at the same time.[5]

Although this chapter will provide basic principles for most of the antibiotic classes commonly used in ICUs, some important antimicrobial agents will not be specifically addressed here, namely macrolides, clindamycin and the antifungal agents.

GENERAL PRINCIPLES

1. All appropriate microbiological specimens, including blood cultures, should be obtained before commencing antibiotic therapy. An immediate Gram-stained report may indicate the appropriate antibiotic to use, otherwise a 'best guess' choice is made depending on the clinical situation. This important and common clinical phenomenon involves trying to predict the infecting organism(s).
2. Blood cultures should be taken from a venepuncture site, after adequate skin antisepsis, and not from an intravenous or arterial catheter. Two *separate* sets of 20 mL (for adults) should be taken, the timing of which is less important.[8] Depending on what system is used, probably 10 mL should be placed into two different blood culture bottles.
3. Once a decision is made to administer antibiotics, they should be administered *without delay*.[9]
4. The decision for empirical therapy (i.e. cover for the most 'likely' organisms causing any specific infection) must include various factors such as: the site of the infecting organism (respiratory tract pathogens differ from those of abdominal infections), community- versus hospital-associated infection, recent previous antibiotic prescription, ward- versus ICU-acquired infection, and knowledge of the organisms commonly grown in patients in any specific area. This latter point is where ward/unit surveillance becomes important.[10,11]
5. Although there should be an attempt to use a narrow-spectrum antibiotic whenever practicable, appropriate therapy particularly for empirical choice for nosocomial sepsis mandates starting off with broad-spectrum antibiotics, even a combination, until culture results are back[12,13] – at which time de-escalation should be embarked upon (see below).[7] Inappropriate[14] and/or delayed correct[9] antibiotic use in the ICU has been shown to impact on morbidity and mortality (**Table 72.1**).[7]
6. Monotherapy with a single agent effective against the expected organisms aims to decrease the risk of drug antagonism, reaction or toxicity.[15]

Table 72.1 New paradigm of treatment for nosocomial sepsis

OLD	NEW
Start with penicillin	Get it right 1st time (broad spectrum)
Cost-efficient low dose	Hit hard up front
Low doses = fewer side effects	Low dose → resistance
Long courses ≥ 2 weeks	Seldom longer than 7 days

From Lipman J, Boots R. A new paradigm for treating infections: "go hard and go home". Crit Care Resusc 2009;11:276–81.

Monotherapy often costs less than multiple antibiotic usage.

7. The clinical response to treatment already given should always be considered when bacteriological results suggest reduced susceptibility.
8. A standard 2-week course of antibiotics is unnecessary and probably harmful. There is a move to use shorter courses for pneumonias[16,17] (see Table 72.1).
9. In consultation with infectious disease specialists, additional tests such as antibiotic minimum inhibitory concentration (MIC), antibiotic assay, serum bactericidal activity and synergy tests of antibiotic combinations may be useful in serious infections (e.g. endocarditis and infections in immunocompromised patients). Susceptibility tests should be interpreted carefully. In vitro sensitivity does not equate with clinical effectiveness; in vitro resistance is a better negative predictor.
10. Consultations with the laboratory staff and infectious diseases/clinical microbiology specialists are always useful and should be mandatory in serious infections (e.g. meningococcal sepsis, meticillin-resistant staphylococci, and multiresistant Enterobacteriaceae).
11. The pharmacokinetics and pharmacodynamics (e.g. penetration into relevant tissues) as well as the spectrum of activity of the antibiotic must be considered. Antibiotic pharmacokinetic principles should determine the dosage and frequency of antibiotic regimens (see below).[18]
12. Adequate drug doses should be given. The intravenous route is preferable in critically ill patients, but other routes should be considered when appropriate.
13. Serum levels of potentially toxic antibiotics should be monitored, especially if hepatic or renal dysfunction is present.
14. Prophylactic use of antibiotics should be limited to certain situations, should cover organisms that potentially can cause infections in that specific group of patients (e.g. organisms causing skin and soft-tissue infections differ from those implicated in intra-abdominal infections) and should be given at the appropriate timing (see below).
15. General signs of infection are signs of systemic inflammation. Although bacterial infection is likely, non-bacterial infection and non-infective causes should also be considered. High procalcitonin and C-reactive protein levels may be discriminatory for infection, but have limitations.[19,20]
16. Antibiotic guidelines are only one aspect of infection control.[21–23] Hand washing and hand hygiene in general are vital and the fundamental aspect of infection control.[21] Identification and elimination of reservoirs of infection,[22,23] blocking transmission of infection,[23] barrier nursing, as well as terminal cleaning of high-touch areas are imperative controls that need to be in place in every ICU.[22,23]

COMMON ERRORS WHEN USING ANTIBIOTICS

1. Administration of antibiotics before microbiological specimens are obtained.
2. Quantity and quality of blood cultures.
3. Extended use of antibiotics after eradication of infection (e.g. a 2-week course for ventilation-associated pneumonia).[16]
4. Antibiotic 'surfing' (i.e. switching from one combination to another) when the patient is not improving without delving into the cause of persistent inflammatory response.
5. Inadequate and delayed therapy and/or incorrect dosing of antibiotics.
6. Failure to adequately predict 'resident' microbial flora and therefore inability to correctly choose empiric antibiotics for nosocomial infections, i.e. no adequate surveillance data.
7. Failure to recognise toxic effects of antibiotics, particularly when polypharmacy is used.
8. Use of combination therapy, irrespective of infection.

SPECIFIC ISSUES

PHARMACOKINETIC PRINCIPLES

The goal of antimicrobial prescription is to achieve effective active drug concentrations (a combination of dose and duration) at the site of infection whilst avoiding, or at least minimising, toxicity.

The various antibiotic classes have different 'kill characteristics' and therefore should be dosed differently[18,24] (**Table 72.2**).

Table 72.2 Pharmacodynamic properties of selected antibiotics

ANTIBIOTICS	Aminoglycosides	Fluoroquinolones Glycopeptides	β-lactams Carbapenems Glycopeptides
PD KILL CHARACTERISTICS	Concentration dependent	Concentration dependent with time dependence	Time dependent
OPTIMAL PK PARAMETER	C_{max} : MIC	AUC : MIC	T>MIC

PD=pharmacodynamics; PK=pharmacokinetic; C_{max}=peak serum concentration; MIC=minimum inhibitory concentration; AUC=area under concentration–time curve; T>MIC=time above MIC.
From Roberts JA, Lipman J. Pharmacokinetic issues for antibiotics in the critically ill patient. Crit Care Med 2009;37:840–51.

β-LACTAMS (ALL PENICILLINS AND CEPHALOSPORINS, MONOBACTAMS)[18,24]

1. Studies of β-lactam antibiotics on Gram-negative bacilli show a bactericidal activity that is relatively slow, time-dependent and maximal at relatively low concentrations. Bacterial killing is almost entirely related to the time that levels in tissue and plasma exceed a certain threshold. The maximum time that plasma β-lactam levels should be allowed to fall below minimum inhibitory concentration (MIC) is 40% of the dosing interval.
2. β-lactam antibiotics lack a significant post-antibiotic effect particularly against Gram-negative organisms, and it is not necessary to achieve very high peak plasma concentrations. Post-antibiotic effect (PAE) is the continued suppression of bacterial growth despite zero serum concentration of antibiotic. It is suggested that concentrations of any β-lactam should be maintained at about 4–5 times MIC for long periods, as maximum killing of bacteria in vitro occurs at this level. If antibiotic concentrations fall below this threshold in the in vitro models, bacterial growth is immediately resumed.[3,4,18,24]
3. Thus, it is important for the efficacy of β-lactams that the dosing regimen maintains adequate plasma levels for as long as possible during the dosing interval. A recent meta-analysis demonstrated that lower doses could be used with continuous infusions for the same outcomes.[25] There is currently one randomised controlled trial that formally addresses the place of continuous infusions of β-lactams.[26]

CARBAPENEMS

1. Similar to β-lactams, the carbapenems also have time-dependent kill characteristics but have some PAE.
2. Prolonged infusions (over 3 hours) have been utilised to improve time above MIC.[27]
3. In vitro data suggest that low concentrations may predispose to development of resistant organisms.[3]

AMINOGLYCOSIDES[18,24]

1. The agents above contrast with the kill characteristic of the aminoglycosides, which is concentration-dependent. Experimentally, a high peak concentration of an aminoglycoside antibiotic provides a better, faster killing effect on standard bacterial inocula.
2. All aminoglycosides exhibit a significant PAE. The duration of this effect is variable, but the higher the previous peak the longer is the PAE. This phenomenon allows drug concentration to fall significantly below MIC of the pathogen without allowing regrowth of bacteria.
3. These principles allow for single daily doses of aminoglycosides (also termed extended interval dosing). Combining various meta-analyses involving thousands of patients, once-daily administration was found to be more efficacious with reduced toxicity, higher peak/MIC ratios, further prolonged PAE and reduced administration costs.
4. With renal dysfunction[28] the dose should be altered according to creatinine clearance. If ≥60 mL/min give 5–7 mg/kg/daily; if 59–40 mL/min, give the same dose at an interval of 36 hours; 39–20 mL/min increases the dosing interval to 48 hours.

QUINOLONES[18,24]

1. Ciprofloxacin, in contrast, has a combination of both of the above characteristics (i.e. concentration-dependent and time-dependent effects), as well as some PAE.
2. Although one suggested ‘target’ parameter for a good clinical bactericidal effect is a high peak, the most validated parameter is the area under the inhibitor curve (AUIC) – that is, AUC/MIC>125.
3. There is general concern about the emergence of resistance related to inappropriately low doses of ciprofloxacin (see Table 72.1).

GLYCOPEPTIDES[18,29]

1. Vancomycin induces a PAE and a post-antibiotic sub-MIC effect. These combined effects suggest that bacterial regrowth will not occur for prolonged periods following a fall in drug concentrations to levels below the MIC.
2. Continuous infusions of vancomycin may have some advantages.

Aminoglycosides and glycopeptides distribute well into fluids of the extravascular, extracellular space, and less well into tissues. This has two important implications. First, these agents should not be first-line agents, or monotherapy, for solid organ infections (lung, kidney, liver, etc.). Secondly, in situations where extravascular fluid shifts are significant (such as in situations of ‘third-space losses’ of abdominal sepsis, in severe burns, etc.), the volume of distribution of these drugs is significantly affected. Hence for any serum level required a larger than usual dose may have to be administered.[29] The volume of distribution of the quinolones (very large) suggests penetration is excellent into most tissues and hence these drugs are good for solid organ infections. Similarly, β-lactams as a group (including carbapenems) all have reasonable tissue penetration.

ANTIBIOTIC PROPHYLAXIS[6,30]

The main indications for prophylaxis are:

- when surgery involves incision through an area of colonisation or normal commensal flora and a resultant potential infection has morbidity or mortality
- when a procedure (e.g. catheterisation, instrumentation, intubation, dental work) potentially produces a bacteraemia in the presence of an immunocompromised patient, or when the potential

bacteraemia occurs in the presence of an abnormal heart valve or a prosthesis.

Basic principles of choice of prophylactic regimen should include the following:

1. The organisms colonising the area through which the incision is made should be covered (Gram-positives if skin is breached, Gram-negatives and anaerobes if bowel is opened).
2. A similar case should be made for colonising organisms through the area breached by catheterisation or instrumentation, etc. (Gram-negatives for bladder catheterisation, Gram-positives and anaerobes for dental procedures).
3. If prevalence of a resistant organism in a specific area is high (e.g. *Pseudomonas* in burns units) then those organisms should be covered by the prophylactic regimen.

TIMING AND DURATION OF PROPHYLAXIS

1. Optimal blood levels of antibiotic(s) are needed when the occurrence of the potential bacteraemia occurs (i.e. for surgery optimal timing of the antibiotic should be at, or just prior to, induction of anaesthesia and skin incision).[30]
2. For prolonged procedures where bacteraemias are still a potential occurrence, a second dose of antibiotic(s) may be considered.
3. There is no extra benefit to postoperative antibiotic prophylaxis.

DOSES[18,29,31]

Comments on dosing regimens are provided below. Doses suggested below are intravenous, for a 70-kg adult with *normal* renal function. All these drugs accumulate with renal dysfunction and modified doses should be used accordingly. It should be noted that some patients with ‘normal’ renal function may have increased renal clearance of antibiotics and hence need a higher than usual dose.[31]

1. Doses for β-lactams vary with each different drug, *but* recent emphasis supports lower boluses with more frequent administration (i.e. 4-hourly versus 8-hourly, or b.d. versus daily).[31] Continuous infusions may become standard practice.[26]
2. *Aminoglycosides:* give tobramycin and gentamicin at 7 mg/kg as a loading dose on the first day, followed by 5 mg/kg/day. Amikacin 25 mg/kg as the loading dose followed by 15 mg/kg/day. These doses are the same for adults and children, neonates excluded.
3. *Quinolones:* the ciprofloxacin dose is *at least* 400 mg b.d. (up to t.d.s.).
4. *Glycopeptides:* the vancomycin[29] dose is at least 30 mg/kg loading and similar/day either as continuous infusion or in divided doses (40 mg/kg/day for children).
5. *Carbapenems:* give meropenem or imipenem at 3 g/day in at least three divided doses.

SURVEILLANCE

Some type of simple laboratory-oriented surveillance, which primarily collects data and resistance patterns of microbiological isolates, is important. Each unit should have access to its own such data as there is an increasing prevalence of resistant organisms in intensive care units. This is complicated even further by different units having differing resistance patterns.[10] Empirical antibiotic therapy must take these factors into account. Some form of surveillance that provides units with their own microbiological data, updateable quarterly or biannually, is therefore beneficial in helping choose empirical and prophylactic regimens that are applicable to any specific unit.[10]

MULTIRESISTANT ORGANISMS

Although this chapter is on antibiotics, the point must be made that without good, efficient and effective infection control policies in all areas treating critically ill patients the spread of multiresistant organisms would be rampant and their control useless.[21–23] Part of these policies should involve attention to good hand hygiene and the use of antiseptic soaps and alcohol-based hand rubs.[21] Hands are still the most documented and incriminated mode of transmission of infection. In this regard a decrement in nursing numbers has also been incriminated in outbreaks of infections possibly due to the time it takes to adequately wash between procedures.[21] High-touch areas are important areas to address with terminal cleaning procedures.[22,23]

1. Multiresistant streptococci and vancomycin-resistant enterococci (VRE), although not common in all countries, are an increasing worldwide problem, as is community-acquired MRSA.
2. New agents are available for treatment of resistant Gram-positive infections.[32]
3. Antibiotic resistance is agent-specific. Often resistance is claimed to be against third-generation cephalosporins, but this is largely to ceftazidime (particularly the extended-spectrum β-lactamases of *Klebsiella pneumoniae, E. coli* and some Enterobacteriaceae).
4. Worrying Gram-negative organisms are *K. pneumoniae, Pseudomonas aeruginosa, Acinetobacter baumanii* spp. *and Stenotrophomonas maltophilia* (the latter specifically, for which trimethoprim may need to be used). A common feature of these organisms is intrinsic resistance to multiple antibiotics. *P. aeruginosa* and *Acinetobacter* complex (also named *A. baumanii*) have become particular problems. Sulbactam and polymyxin B or colistin have been used for these problem organisms.
5. Although the antibiotic pipeline is drying up, there are some new agents on the horizon.[33]

MONO- VERSUS COMBINATION THERAPY[12,13,15]

1. Much of the work in this area was performed before the clinical introduction of the carbapenems, penicillin/β-lactamase combinations and fourth-generation cephalosporins. It seems that newer single agents are adequate, apart possibly from resistant pseudomonal infections.[15]
2. There is no clear evidence supporting the claim that combination antimicrobial therapy prevents emergence of resistance.[15]
3. However, combination therapy is often suggested for endocarditis and some pseudomonal infections.[13] When combination therapy is used, preference should be given to the combination therapy of two different classes of antibiotics that act synergistically. The combination of two β-lactam antibiotics should not be used.

BROAD-SPECTRUM INITIAL COVER WITH DE-ESCALATION[7,13,14]

In view of the morbidity and mortality of delayed appropriate therapy for nosocomial sepsis,[9,14] patients with risk factors for infection with resistant pathogens should initially receive broad-spectrum antibiotics, possibly even combination therapy,[7,13,14] then, as soon as the pathogen and the susceptibilities are available, treatment should be simplified to a more targeted one – so-called 'de-escalation' therapy (see Table 72.1).[7] In the limited studies to date, de-escalation has led to less antibiotic usage, shorter durations of therapy, fewer episodes of secondary pneumonia and reduced mortality, without increasing the frequency of antibiotic resistance.

TIME TO ANTIBIOTICS AS A QUALITY INDICATOR

Recent data suggest that, particularly in septic shock, a delay of even hours of appropriate antibiotic administration increases morbidity and mortality.[9] A delay in antibiotic administration has therefore become an important negative factor in patient outcomes. Similar to the concept of 'time to lysis', antibiotic administration from the time of recognition of infection may in future become a quality indicator of infection management.

Tropical diseases

Ramachandran Sivakumar and Michael E Pelly

Once an exotic and esoteric topic, modern travel and the quest for unusual holidays has the potential to bring tropical diseases to every ICU. This chapter covers some important diseases, which are common in the tropical belt.

MALARIA

EPIDEMIOLOGY AND PATHOGENESIS

It is estimated that four species of *Plasmodium* (*vivax*, *malariae*, *ovale* and *falciparum*) cause 200 to 300 million infections per year. Most of the 600–700 000 deaths per year due to malaria are caused by *P. falciparum* and the majority of deaths are in children under 5 years of age in sub-Saharan Africa. Malaria is also widely prevalent in the Indian subcontinent and South-East Asia. It is transmitted from human to human by the bite of infected female *Anopheles* mosquitoes. After development in the liver, there is invasion of red cells by parasites, which is followed by their multiplication, and rupture of the red cells. The cycle is then repeated in red cells. In *vivax* and *ovale* infections, development to dormant forms can occur in the liver, which may lead to relapse.

CLINICAL FEATURES

UNCOMPLICATED MALARIA

Initial symptoms of malaria are non-specific and similar to a viral illness. Classic symptoms of fever, aches and headache are usually, but not always, present. Other features such as diarrhoea, vomiting, cough and abdominal pain may confuse the unwary. Unusual presentations are more common in children and may be missed. Classical rigors or fevers occurring on specific days (tertian or quartan) are usually absent in early *falciparum* infection. Clinical signs may be unhelpful, although hepatosplenomegaly may be present fairly early.

SEVERE MALARIA

Risk factors for severe malaria[1]

- Children under 5 years in endemic regions
- Adults and children in areas of low endemicity
- Non-immune travellers to endemic areas.

Definition

Clinical features include:

- impaired consciousness or unrousable coma
- prostration (i.e. generalised weakness so that the patient is unable walk or sit up without assistance)
- failure to feed
- multiple convulsions – more than two episodes in 24 hours
- deep breathing, respiratory distress (acidotic breathing)
- circulatory collapse or shock, systolic blood pressure <70 mmHg (9.31 kPa) in adults and <50 mmHg (6.65 kPa) in children
- clinical jaundice plus evidence of other vital organ dysfunction
- haemoglobinuria
- abnormal spontaneous bleeding
- pulmonary oedema (radiological).

Laboratory findings include:

- hypoglycaemia (blood glucose <2.2 mmol/L or <40 mg/dL)
- metabolic acidosis (plasma bicarbonate <15 mmol/L)
- severe normocytic anaemia (Hb <5 g/dL, packed cell volume <15%)
- haemoglobinuria
- hyperparasitaemia (>2%/100 000/μL in low-intensity transmission areas or >5% or 250 000/μL in areas of high stable malaria transmission intensity)
- hyperlactataemia (lactate >5 mmol/L)
- renal impairment (serum creatinine >265 μmol/L).

The incubation period is 7 days (usual range 9–14 days), but this may be prolonged. Several of the above coexist or may develop in rapid succession. Cough, convulsions and hypoglycemia are more common in children. Jaundice is common, but hepatic failure is uncommon. The acidosis of malaria is multifactorial and probably very similar to other forms of sepsis involving tissue hypoxia, liver dysfunction and impaired renal handling of bicarbonate.

The differential diagnosis of malaria includes:

- meningitis, typhoid fever, septicaemia
- severe influenza, dengue and other arboviral infections
- haemorrhagic fevers

- hepatitis, leptospirosis
- rickettsial diseases (e.g. scrub typhus)
- relapsing fever (*Borrelia recurrentis*)
- febrile convulsions in children.

Pregnancy increases the risk of development of severe malaria. During pregnancy both maternal and fetal morbidity and mortality are increased.

Poor prognostic indicators include age under 3 years, cerebral malaria, circulatory collapse and organ dysfunction. Laboratory evidence of poor prognosis includes hyperparasitaemia (>250 000/μL or >5%), peripheral schizontaemia, severe anaemia (PCV < 15% or Hb < 50 g/L), raised blood urea >60 mg/dL and serum creatinine >265 μmol/L (>3.0 mg/dL), raised venous lactate (>5 mmol/L), raised CSF lactate (>6 mmol/L), low CSF glucose and a very high concentration of TNF-α.

Cerebral malaria

Cerebral malaria may be the most common non-traumatic encephalopathy worldwide. The term is restricted to the syndrome in which altered consciousness due to malaria could not be attributed to convulsions, sedatives, hypoglycaemia or to a non-malarial cause.

Clinical, histopathological and laboratory studies have suggested two potential mechanisms:

- *mechanical hypothesis:* cytoadherence of parasitised erythrocytes
- *cytotoxic hypothesis:* neuronal injury by malarial toxin and excessive cytokine production.

Cerebral malaria has few specific features, but there are differences in clinical presentation between African children and non-immune adults.[2]

Clinical findings include:

- coma
- convulsions
- raised intracranial pressure
- hypoglycaemia
- acidosis
- abnormalities of tone and posture (the commonest being symmetrical pyramidal signs)
- retinopathy – retinal haemorrhages, cotton wool spots, papilloedema, retinal whitening and retinal vessel abnormalities – all of which are more common in children.

DIAGNOSIS

- Microscopy of thick and thin films remains the gold standard for both the diagnosis, and to follow the efficacy of treatment. In the non-immune patient there is a close association between parasite levels and complications; however, severe complications can occur in patients with low counts.
- Rapid diagnostic tests (RDT) that detect specific antigens (proteins) produced by malaria parasites are useful in diagnosis. Current tests are based on the detection of histidine-rich protein 2 (HRP2) (which is specific for *P. falciparum*), pan-specific or species-specific parasite lactate dehydrogenase (pLDH) or other pan-specific antigens such as aldolase. Many commercial assays are available. Some tests detect only one species (*P. falciparum*), whereas others detect one or more of the other three species. RDTs do not give information about the parasite load and their sensitivity and specificity decrease at low parasitaemia. Hence, it is important to seek microbiological advice regarding the RDT tests used locally.
- PCR tests based on detecting malarial DNA are more sensitive than microscopy but are expensive and do not give estimates of parasite load.
- In areas where two or more species of malaria parasites are common, only microscopy will permit a species diagnosis. Where mono-infection with *P. vivax* is common and microscopy is not available, it is recommended that a combination RDT, which contains a pan-malarial antigen, is used. Where *P. vivax, P. malariae* or *P. ovale* occur, almost always as a co-infection with *P. falciparum*, an RDT detecting *P. falciparum* alone may be sufficient; the treatment for non-*falciparum* malaria is given only to cases with a negative test result and where no other obvious cause of illness is present. Treatment solely on the basis of clinical suspicion should only be considered when a parasitological diagnosis is not accessible.

TREATMENT OF MALARIA[3]

WHO has recently issued new guidelines for the treatment of malaria.

FALCIPARUM MALARIA (Box 73.1)

To counter the threat of resistance of *P. falciparum* to monotherapies, and to improve treatment outcome, combinations of antimalarials are now recommended by WHO for the treatment of falciparum malaria. Antimalarial combination therapy is the simultaneous use of two or more blood schizontocidal drugs with independent modes of action. Artemisinin-based combination therapy (ACT) is recommended treatment for uncomplicated falciparum malaria. The choice of ACT in a country or region will be based on the level of resistance of the partner medicine in the combination.

Severe falciparum *malaria* (Box 73.2)

Two classes of drugs are currently available for the parenteral treatment of severe malaria: the cinchona alkaloids (quinine and quinidine) and the artemisinin derivatives (artesunate, artemether and artemotil). Recent evidence[4,5] suggests superior efficacy of artesunate over quinine in adults. The dosage of artemisinin

Box 73.1 WHO recommendations for treatment of uncomplicated *P. falciparum* malaria

Artesunate + amodiaquine
4 mg/kg of artesunate and 10 mg base/kg of amodiaquine given once a day for 3 days
Artesunate + sulfadoxine–pyrimethamine
4 mg/kg of artesunate given once a day for 3 days and a single administration of sulfadoxinepyrimethamine (25/1.25 mg base/kg bw) on day 1
Artesunate + mefloquine
4 mg/kg of artesunate given once a day for 3 days and 25 mg base/kg of mefloquine usually split over 2 or 3 days
Artemether–lumefantrine
They are available as co-formulated tablets containing 20 mg of artemether and 120 mg of lumefantrine; the recommended treatment for persons weighing more than 34 kg is 4 tablets twice a day for 3 days
Dihydroartemisinin plus piperaquine
4 mg/kg/day dihydroartemisinin and 18 mg/kg/day piperaquine once a day for 3 days
Second-line antimalarial treatment
Artesunate (2 mg/kg once a day) plus doxycycline (3.5 mg/kg once a day) or clindamycin (10 mg/kg twice a day) for 7 days
Quinine plus doxycycline or clindamycin for 7 days

Box 73.2 WHO recommendations for treatment of severe falciparum malaria

Artesunate
2.4 mg/kg i.v. or i.m. given on admission (time = 0), then at 12 hours and 24 hours, then once a day
Artemether, or quinine, is an acceptable alternative if parenteral artesunate is not available: artemether 3.2 mg/kg BW i.m. given on admission, then 1.6 mg/kg BW per day; or quinine 20 mg salt/kg BW on admission (i.v. infusion or divided i.m. injection), then 10 mg/kg BW every 8 hours; infusion rate should not exceed 5 mg salt/kg BW per hour
Give parenteral antimalarials in the treatment of severe malaria for a minimum of 24 hours, once started (irrespective of the patient's ability to tolerate oral medication earlier) and, thereafter, complete treatment by giving a complete course of one of the regimens listed in Box 73.1 except artesunate + mefloquine regimen

derivatives does not need adjustment in vital organ dysfunction.

In patients with features of severe malaria, a mixed infection with *P. falciparum* should be assumed even if only a benign species is identified in the film. Occasionally, severe malaria can occur with *P. vivax* species. If clinical suspicion is high, a therapeutic trial of antimalarial treatment is justified even if the film is negative.

Box 73.3 WHO recommendations for treatment of *P. vivax*, *ovale* and *malariae* malaria

Uncomplicated *P. vivax* malaria
Chloroquine 25 mg base/kg divided over 3 days, combined with primaquine 0.25 mg base/kg, taken with food once daily for 14 days is the treatment of choice for chloroquine-sensitive infections; in Oceania and South-East Asia the dose of primaquine should be 0.5 mg/kg
For chloroquine-resistant *vivax* malaria, ACTs combined with primaquine except artesunate plus sulfadoxine–pyrimethamine as this is not effective against *P. vivax* in many places
Complicated *P. vivax* malaria
Treatment is the same as severe *P. falciparum* malaria
***P. ovale* and *malariae* malaria**
Treatment is the same as uncomplicated *P. vivax* malaria but without primaquine for *P. malariae*

Severe malaria leads to severe septic shock, and the principles of management are the same, including resuscitation and provision of supportive treatment. These patients are at risk of acute lung injury but do need adequate fluid resuscitation. Convulsions must be actively treated. Complications should be managed as they present. The threshold for dialysis should be low. Pneumonia and bacterial septicaemia are also common, and should be recognised and treated.

Exchange blood transfusion (EBT) has been used in severe malaria. However, recent WHO guidelines[3] do not make any recommendation and note the lack of consensus on indications, benefits and dangers involved, or on practical details such as the volume of blood that should be exchanged. Traditional indications for EBT if pathogen-free compatible blood is available are:

- parasitaemia >30% even in the absence of clinical complications
- parasitaemia >10% in the presence of severe disease, especially cerebral malaria, acute renal failure, ARDS, jaundice and severe anaemia and/or poor prognostic factors (e.g. elderly patient, late-stage parasites (schizonts) in the peripheral blood)
- parasitaemia >10 % and failure to respond to optimal chemotherapy after 12–24 hours.

OTHER FORMS OF MALARIA (Box 73.3)

PROGNOSIS

Data are largely derived from endemic areas where presentation with convulsions, acidosis or hypoglycaemia is associated with a poorer outcome. Mortality in artesunate-treated severe *falciparum* malaria group in one trial[5] was still high (15% vs 22% in quinine-treated patients). In cerebral malaria, mortality is

around 20%. The prognosis of cerebral malaria is frequently determined by the management of other complications such as renal failure and acidosis, but neurological sequelae are increasingly recognised.

TUBERCULOSIS

EPIDEMIOLOGY

Tuberculosis continues to be a devastating disease worldwide, with an estimated 9 million new cases and 1.5 million deaths annually. Medical conditions that predispose to tuberculosis include HIV infection, silicosis, diabetes, chronic renal failure/haemodialysis, malnutrition, solid organ transplant, gastrectomy, jejunoileal bypass, injection and inhalational drug abuse, alcoholism, chronic pulmonary disease, and prolonged steroid use. Social factors such as institutional living conditions (nursing homes, homeless shelters, prisons), urban dwelling and poverty are associated with an increased risk of tuberculosis.

PATHOGENESIS

Tuberculosis is usually caused by *Mycobacterium tuberculosis* and four other species (*M. bovis*, *M. africanum*, *M. microti* and *M. canetti*) grouped in the *Mycobacterium* complex. The genus *Mycobacterium* consists of many different species, all of which appear similar on acid-fast staining.

Inhalation of tubercle bacilli leads to one of four possible outcomes: immediate clearance of the organism, primary or progressive primary disease, chronic or latent infection, and reactivation disease. Latent infection refers to the presence of tuberculous infection (positive tuberculin reaction) without the disease.

The majority of primary TB infections are asymptomatic; clinical pneumonia occurs in 5–10% of adults, with a higher incidence in children and those suffering HIV infection. *M tuberculosis* microfoci that have remained dormant after primary infection may undergo reactivation resulting in secondary TB, often referred to as reactivation disease. This is responsible for 90% of TB in patients not infected with HIV.

CLINICAL SPECTRUM

The manifestations of TB are protean and TB should be considered in the differential diagnosis of all patients with fever of unknown origin, night sweats or unexplained weight loss. Besides the lungs, it can also involve the central nervous system, peritoneum, pericardium, gastrointestinal and genitourinary tract, bone and joints, lymph nodes and skin. Occasionally it can be disseminated in the form of miliary tuberculosis.

PULMONARY TUBERCULOSIS

Typically reactivation disease starts in the apex of one or both lungs leading to chronic inflammation and fibrosis. Pulmonary TB is often asymptomatic initially, though cough, dyspnoea and haemoptysis are useful clues. Hilar lymphadenopathy is the most common pulmonary presentation in children. It may occasionally present very late as extensive disease in both lungs with severe lung damage including cavitation and pneumothoraces.

Sputum, induced sputum, bronchial washings and transbronchial biopsy of infiltrates should be performed to isolate the organism. Computed tomography (CT) is more sensitive than chest radiography for detection of infiltrates, cavities, lymphadenopathy, miliary disease, bronchiectasis, bronchial stenosis, bronchopleural fistula and pleural effusion.

Tuberculous pleural effusion

Pleural TB may result in pleural effusion, or pleural empyema with or without bronchopleural fistula. Thoracentesis and pleural biopsy should be performed. The pleural fluid should be examined for total protein and glucose content, WBC count and differential, and fluid pH.

Positive cultures are found in less than 25% of cases. Pleural biopsy shows granulomatous inflammation in approximately 60% of patients. However, when culture of three biopsy specimens is combined with histological examination, the diagnosis can be made in up to 90% of cases. Pleuroscopy-guided biopsies increase the yield in pleural sampling. Conventional diagnostic tests have limitations.[6] Raised adenosine deaminase (ADA) levels have been found to be useful in the diagnosis with levels more than 70 U/L in pleural fluid strongly favouring tuberculous aetiology and levels less than 40 U/L making it less likely; ADA also has a good negative predictive value. However ADA assay should not be considered as an alternative to biopsy and culture.[7] Raised γ-interferon has also been found to be useful. Nucleic acid amplification tests have high specificity but low and variable sensitivity. Hence these tests are useful in confirming the disease, but not useful in excluding the disease.

TUBERCULOUS MENINGITIS

Tuberculous meningitis[8] remains the most serious relevant manifestation of TB to the intensive care physician. Tuberculous meningitis results from haematogenous spread. There is a thick gelatinous exudate around the sylvian fissures, basal cisterns, brainstem and cerebellum.

The majority of patients with TB meningitis have had recent contact with TB, followed by a prodrome of vague ill-health lasting 2–8 weeks. Later, signs and symptoms of meningeal irritation appear. Cranial nerve palsies occur in 20–25% of patients and papilloedema may be present. Choroidal tubercles are rare but almost pathognomonic. Visual loss due to optic nerve involvement may occasionally be the presenting feature. There may be focal neurological deficit such as

hemiplegia; extrapyramidal movements and seizures are other manifestations. As the disease progresses, cerebral dysfunction sets in and the mortality approaches 50%.

Diagnostic algorithms have been suggested but they are unlikely to provide sufficient assurance to confidently exclude other diagnoses.[9,10] The key is a high degree of clinical suspicion, especially in the critically ill. In one study, TB meningitis was considered as a diagnosis in only 36% of cases and only 6% received immediate treatment.[11]

Definitive diagnosis of TB meningitis depends upon the detection of the organism in CSF, either by smear examination or by bacterial culture. The yield from smear is variable, but generally low. Culture of the CSF for the organisms is not invariably positive. Raised adenosine deaminase level is not specific. Various molecular-based methods including nucleic acid amplification (NAA) assays have emerged as a promising new method for the diagnosis of CNS tuberculosis because of its rapidity, sensitivity and specificity. In particular, nested PCR assay technique may improve the diagnosis of CNS tuberculosis.[12]

Computed tomography (CT) or magnetic resonance imaging (MRI) of the brain, both of which are sensitive but not specific, may reveal thickening and intense enhancement of meninges especially in basilar regions. Hydrocephalus and tuberculomas may also be present. Infarcts due to either vasculitis or mechanical strangulation of the vessels by the surrounding exudates are detected in up to 40%. The radiological differential diagnosis includes cryptococcal meningitis, CMV encephalitis, sarcoidosis, meningeal metastases and lymphoma.

TUBERCULOUS EMERGENCIES

- Massive haemoptysis
- Respiratory failure
- Pericardial tamponade
- Small intestinal obstruction
- Tuberculous meningitis
- Status epilepsy due to tuberculomas.

DIAGNOSIS OF TUBERCULOSIS

Once considered, isolate the patient and sample all potential sites for acid-fast staining and culture. Pleural, peritoneal, pericardial and other fluids must be cultured and analysed for differential cell count, protein, glucose and adenosine deaminase.

Histological examination for granulomatous infection is useful in bronchial tissue, pleural, peritoneal and skeletal tissues. Peritoneal biopsies are best obtained via laparoscopy. Newer culture media have reduced the time for culture to 2 weeks.

Nucleic acid amplification (NAA) tests amplify target nucleic acid regions that uniquely identify the *M. tuberculosis* complex, and are available as commercial kits or in-house assays. They can be applied to clinical specimens within hours. Based on current evidence, NAA tests cannot entirely replace conventional diagnostic approaches using microscopy and culture. A sensitive and specific fully automated and commercially available NAA Xpert MTB/RIF assay (Cepheid, Sunnyvale, CA, USA) can produce results in less than 2 hours, permitting a specific tuberculosis diagnosis and rapid detection of rifampicin resistance.[13]

The current status of NAA tests is summarised below:

- NAA tests, in general, have high specificity and positive predictive value; they are useful in ruling in rather than ruling out TB.
- A positive NAA test in smear-positive patients can differentiate *M. tuberculosis* from non-tuberculous *Mycobacteria* (NTM); treatment can then be started.
- The interpretation of smear-positive but negative-NAA test is controversial.
- In smear-negative and NAA-positive patients with a high clinical suspicion, treatment can be started particularly when prompt treatment is imperative.
- If clinical suspicion is high, TB is not excluded by both a negative smear and NAA.
- NAA results may remain positive for months. This method should be used only for initial diagnosis and not for follow-up.

Serodiagnosis of tuberculosis, despite remaining as a poor confirmatory tool, may be useful in exclusion of disease in areas of low incidence. The tuberculin skin test is useful in the diagnosis of latent infection with tuberculosis, but it cannot reliably distinguish individuals infected with *M. tuberculosis* from individuals sensitised to other mycobacteria including BCG. Interferon-γ release assays (IGRAs) are at least as sensitive and more specific than the tuberculin skin test. These IGRAs show high sensitivities but low specificities and hence can be used as rule out, but not rule in, tests for diagnosis of active tuberculosis.[14] Drug susceptibility tests should be performed on initial isolates from all patients in order to identify an effective antituberculous regimen, and may have to be repeated if the patient remains culture positive after 3 months.

TREATMENT OF TUBERCULOSIS[15]

Local guidelines are of paramount importance and advice should be sought. The commonest regimen used is isoniazid (5 mg/kg; max. 300 mg daily), and rifampicin (10 mg/kg; max. 600 mg daily) for 6 months with the addition of pyrazinamide (25 mg/kg) and ethambutol (15 mg/kg) for the first 2 months. It has been suggested that, instead of ethambutol, streptomycin is preferable as a fourth drug in tuberculous

meningitis. Steroids are generally recommended in tuberculous meningitis and pericardial tuberculosis.

DRUG-RESISTANT TUBERCULOSIS

This is an increasing problem. Multidrug-resistant tuberculosis (defined as resistance to two or more of the first-line antituberculous drugs, usually INH and rifampicin) can be primary (no prior antituberculous therapy) or secondary (development of resistance during or after chemotherapy). Extensively drug-resistant (XDR) tuberculosis, defined by additional resistance to two second-line drug classes, is more difficult to treat and may be incurable.

Diagnosis depends upon collection of adequate specimens for culture prior to the initiation of antituberculous therapy. In critically ill patients, rapid diagnosis of drug resistance is of paramount importance. With the improvements in the culture methods and the availability of newer techniques, rapid identification of resistance is possible.[13] When resistance is present to two or more first-line agents, parenteral aminoglycoside (streptomycin, amikacin, etc.) and fluoroquinolones are generally added. Specialist microbiological advice should be sought.

TYPHOID FEVER

Typhoid fever is caused by *S. typhi* and less commonly by paratyphi A, B and C. Even non-typhoidal salmonellae have occasionally been isolated.[16] Typhoid fever, common in South and South-East Asia, is almost exclusively caused by fecal–oral spread. In the developed world, cases are either seen in international travellers or occasionally caused by infected food.

CLINICAL FEATURES

The incubation period is 5–21 days. Typhoid presents non-specifically with fever, chills, abdominal pain and constitutional symptoms. Constipation may be more frequent than diarrhoea. Hepatosplenomegaly, erythematous macular rash (30%) and relative bradycardia may be present. Relative bradycardia is not specific for enteric fever, but is a useful clue.[17]

COMPLICATIONS

- Shock
- Intestinal perforation
- Gastrointestinal haemorrhage
- Jaundice and encephalopathy[18]
- Neuropsychiatric manifestations
- Septic arthritis, pericarditis, etc.
- Obstetric complications in pregnant women.

DIAGNOSIS[19]

Anaemia, leucopenia/leucocytosis and deranged liver function are common. Blood cultures are positive in up to 80% of cases, and are the investigation of choice; 10–15 mL yields higher success than smaller volumes.[20] Though culturing urine, stool, rose spots and duodenal contents are useful, bone marrow culture is the most sensitive, and its yield remains unchanged up to 5 days after commencement of treatment.[21]

Serodiagnosis using Widal tests has limited clinical value. Commercial serological tests such as Typhidot-M® and Tubex®, which detect IgM antibodies against different *S typhi* antigens, have a higher sensitivity and specificity.[22] Nested PCR is very promising in the diagnosis of typhoid fever.

TREATMENT[23]

In both uncomplicated and complicated typhoid fever, the treatment of choice is fluoroquinolones (ciprofloxacin or ofloxacin for 5–7 days in uncomplicated and 10–14 days in complicated infections). In fluoroquinolone-resistant cases, azithromycin, cefixime or ceftriaxone can be used. There is some concern in using fluoroquinolones in children as they have been shown to cause cartilage toxicity in immature animals, but this appears largely unfounded in clinical trials.[24] A recent Cochrane review reported that, when compared with fluoroquinolones, azithromycin significantly reduced clinical failure.[25]

Dexamethasone reduces mortality in severe typhoid fever: delirium, obtundation, stupor, coma or shock. [26] Ileal perforation, which may occur late, classically in the third week of febrile illness, requires prompt surgical intervention, and segmental resection has been recommended as the procedure of choice. [27,28]

CHOLERA

Cholera is caused by enterotoxin-producing *Vibrio cholera*.[29] The incubation period varies from 12 hours to several days. The clinical case : infection ratio is about 1 : 10. It starts abruptly with painless watery diarrhoea associated with vomiting and painful muscle cramps. Vomiting may be the first symptom before diarrhoea.

Stool examination shows neither leucocytes nor erythrocytes. Dark-field microscopy examination may reveal rapidly motile comma-shaped bacilli in fresh stool. Commercial assays detecting O antigen in stool samples, which take less than 5 minutes, are now available and are as sensitive and specific as stool culture. Aggressive rehydration is the mainstay of treatment; very large quantities of fluid may be needed. Adjunctive antimicrobial therapy is effective in shortening the duration of diarrhoea. Single-dose doxycycline (300 mg) or single-dose ciprofloxacin (1 g) is very effective, but azithromycin has recently been shown to be superior.[30]

LEPTOSPIROSIS

This is caused by *Leptospira interrogans*. It occurs due to exposure to contaminated water. The disease has an

incubation period of 7–10 days with a range of 2–20 days. It has two phases: septicaemic phase and immune phase. Clinical features include conjunctival suffusion or haemorrhages (useful diagnostic clue), uveitis, severe muscle tenderness, non-oliguric renal failure, hypokalaemia, hepatic dysfunction, pulmonary haemorrhage, ARDS, myocarditis, rhabdomyolysis, thrombocytopenia, DIC, haemorrhage into the skin and internal organs, and digital gangrene. Weil's syndrome is characterised by hepatorenal dysfunction, bleeding diathesis and pulmonary involvement.

Diagnosis is made with isolation of the organism by culture (blood, urine, CSF) or serology using the gold standard microscopic agglutination test (MAT). Alternative serology tests including ELISA tests are available. Both culture and serology should be attempted if available, and local microbiological advice should be sought. Treatment is with penicillin G or ceftriaxone. In penicillin-allergic patients, doxycycline can be used.

DENGUE FEVER

EPIDEMIOLOGY AND PATHOGENESIS

It is estimated that 50 million cases of dengue fever occur worldwide annually and half a million people suffering from DHF require hospitalisation each year, a very large proportion of whom (approximately 90%) are children less than 5 years old.[31] The causative agent is a flavivirus with four distinct serogroups, and it is transmitted by the bite of *Aedes* mosquitoes. Two patterns of transmission have been recognised, epidemic due to isolated introduction of dengue to a region, usually due to a single serotype, and hyperendemic referring to the continuous circulation of multiple dengue virus serotypes.

Following a mosquito bite, viraemia begins and usually lasts up to 7 days. Infection with one of the four serotypes (primary infection) provides life-long immunity against that serotype, but not against the other serotypes (secondary infection). Epidemiological studies have suggested that the risk of severe disease (DHF/DSS) is significantly higher in secondary infection than in primary infection.

CLINICAL FEATURES

The clinical presentation varies from mild febrile illness to severe haemorrhagic fever. Most infections are asymptomatic. WHO classifies dengue infection as undifferentiated fever, dengue fever (DF), and dengue haemorrhagic fever (DHF)/dengue shock syndrome (DSS).[31]

Dengue fever has an incubation period of 3–14 days and is characterised by the sudden onset of fever, severe headache, retro-orbital pain on moving the eyes, and fatigue. It is often associated with severe myalgia and arthralgia (breakbone fever). Maculopapular rash, flushed facies and injected conjunctiva are common. Haemorrhagic manifestations can occur in DF and should not be confused with DHF.

Dengue haemorrhagic fever occurs primarily in children <10 years and is characterised by plasma leakage syndrome and haemoconcentration (20% or greater rise in haematocrit), pleural effusion or ascites. The diagnosis is made if the following symptoms and signs are present: bleeding, a platelet count of less than 100 000 per cubic millimetre, and plasma leakage. Haemorrhagic manifestations without evidence of plasma leakage do not constitute DHF. The mechanism underlying the profound capillary leak in DHF but not in DF is poorly understood. It is important to watch for the onset of DHF, which typically occurs 4–7 days after the onset of the disease, approximately at the time of defervescence. Decrease in platelet count and rise in haematocrit are useful clues.[32]

Dengue shock syndrome is characterised by profound hypotension and shock.

DIAGNOSIS

Dengue should be suspected in all febrile patients who live in, or have returned from, endemic areas in the preceding 2 weeks. Leucopenia, thrombocytopenia with a positive tourniquet test and raised AST are frequently seen; the former two tests have the highest sensitivity (about 90%) for the diagnosis of early dengue.[32] A positive tourniquet test alone cannot differentiate DHF from DF.

IgM immunoassay allows rapid confirmation of the diagnosis. If it is negative, particularly in the first 6 days of the illness, the diagnosis should not be ruled out. Acute and convalescent sera should be analysed by haemagglutination assay or IgG immunoassay for a fourfold rise in titre. Virus isolation, viral nucleic acid detection by techniques such as reverse transcriptase PCR, and viral antigen detection are available.[31]

TREATMENT

Supportive therapy for shock, especially appropriate and prompt fluid replacement can reduce mortality. Fluid management is complex and WHO guidelines on fluid management are available.[31] In DSS, steroids have not been shown to be useful.[33] Once capillary leakage abates, fluid overload and pulmonary oedema can become problematic.

HANTAVIRUS

Hantaviruses are rodent viruses distributed worldwide, with over 150 000 cases being registered annually. There are two major clinical syndromes: haemorrhagic fever with renal syndrome (HFRS) and hantavirus cardiopulmonary syndrome (HCPS). Both are acquired by exposure to aerosols of rodent excreta.

HANTAVIRUS CARDIOPULMONARY SYNDROME

The incubation period is about 3 weeks. There are two phases: the prodromal phase is characterised by a relatively mild febrile illness, typically lasting 3–5 days, and the cardiopulmonary phase is characterised by severe, rapidly progressive respiratory failure. In the latter phase, acute pulmonary oedema due to increased capillary permeability occurs. The progress from the prodromal phase to cardiopulmonary phase is dramatic. In severe cases, significant myocardial depression also occurs, resulting in low cardiac output and hypotension. Acute renal failure can occur. The combination of thrombocytopenia, myelocytosis, haemoconcentration, lack of significant toxic granulation in neutrophils, and more than 10% of lymphocytes with immunoblastic morphological features is highly sensitive and specific. ELISA for IgM and IgG antibodies is useful in the diagnosis. Hantavirus can also be detected by tissue RT-PCR. Immunohistochemical staining of tissue reveals hantaviral antigen. Treatment is mainly supportive with intravenous fluids, inotropes, mechanical ventilation, extracorporeal membrane oxygenation and blood products. Intravenous ribavirin is probably ineffective in the treatment of HCPS in the cardiopulmonary stage.[34]

HAEMORRHAGIC FEVER WITH RENAL SYNDROME

This is characterised by fever, renal failure and haemorrhagic manifestations. The disease has five progressive stages: febrile, hypotensive, oliguric, diuretic and convalescent. Non-specific constitutional symptoms are followed by shock, oliguria, disseminated intravascular coagulation (DIC) and haemorrhagic manifestations. Diagnosis is made using ELISA for IgG and IGM antibodies. Treatment is supportive, including renal support. Ribavirin has been found to be useful.[35]

ARBOVIRAL ENCEPHALITIS

Viruses transmitted to human beings by the bites of arthropods (especially mosquitoes and ticks) are major causes of encephalitis worldwide. Although different viruses can cause encephalitis, an antigenically related group of flaviviruses[36] accounts for a major proportion of cases worldwide. These include mosquito-borne diseases such as Japanese encephalitis, West Nile virus encephalitis, St Louis encephalitis, Murray Valley encephalitis[37] and tick-borne encephalitis.[38] Viral encephalitis is characterised by a triad of fever, headache and altered level of consciousness. Other common clinical findings include disorientation, behavioural and speech disturbances, and focal or diffuse neurological signs such as hemiparesis or seizures. The incubation period is usually 5–15 days. Other manifestations include recurrent seizures, including status epilepticus, a flaccid paralysis resembling that of poliomyelitis, and Parkinsonian-type movement disorders. Flavivirus encephalitis is diagnosed usually by the IgM capture enzyme-linked immunosorbent assay (ELISA). Treatment is supportive. Interferon-α, ribavirin and intravenous immunoglobulin have all been tried with mixed success.

VIRAL HAEMORRHAGIC FEVERS (VHF)

Viral haemorrhagic fever is a general term for a severe illness, sometimes associated with bleeding, caused by a number of viruses.

EPIDEMIOLOGY

Lassa virus, Rift Valley fever, Crimean–Congo HF, haemorrhagic fever with renal syndrome (HFRS-hantavirus), Marburg and Ebola virus, yellow fever and dengue haemorrhagic fever are some of the most important viral haemorrhagic fevers. Haemorrhagic fever viruses have an affinity for the vascular system and increased vascular permeability is the primary defect. Petechial haemorrhages are usually associated with fever and myalgias. Later, frank mucous membrane haemorrhage may occur, with accompanying hypotension, shock and circulatory collapse. Multisystem organ failure can occur. There is a wide variation in the relative severity of the clinical presentation.

The sources of infection are rodents for Lassa virus and hantavirus, mosquitoes for Rift Valley fever, yellow fever and dengue haemorrhagic fever, and ticks for Congo–Crimean haemorrhagic fever virus. At least four of the haemorrhagic fevers – Lassa fever (LF), Ebola virus, Marburg virus and CCHF – are capable of person-to-person transmission through close contact with infected blood and other body secretions. Epidemiological studies of VHF in humans indicate that although possible, the airborne route does not readily transmit infection from person to person.

CLINICAL FEATURES

The patient will have either been in an endemic area or been in contact with someone from an endemic area.

Viral haemorrhagic fevers[39] generally have an abrupt onset with an incubation period <10 days. The incubation period can be up to 21 days. They present as acute febrile illnesses with a prodrome that often includes severe headache, dizziness, flushing, conjunctival injection, myalgia, lumbar pain and prostration. Gastrointestinal symptoms with nausea, vomiting, abdominal pain and diarrhoea may occur.

Leucopenia or leucocytosis, thrombocytopenia and elevated serum aminotransferases may be evident early in the disease; a petechial rash may appear on days 3–10. Coagulation profiles become progressively more abnormal, and overt haemorrhagic features of the disease (ecchymoses, epistaxis, gingival bleeding,

malaena, haematuria, etc.) may supervene from day 5 onward, or sometimes even earlier. Multiple organ failure supervenes and death may ensue. Clinical improvement becomes apparent toward the end of the second week of illness in patients who survive.

DIAGNOSIS

A high index of suspicion is needed and VHF should be suspected in the following circumstances:

- unexplained fever in patients who have visited areas where VHF are endemic, within 3 weeks of becoming ill; the likelihood is greater if they have camped in the bush, slept on the ground or in rural farms, or had any bites or contact with sick animals
- febrile medical and nursing staff in the endemic areas and laboratory workers who handle VHF viruses
- febrile contacts.

Tests on samples present an extreme biohazard risk. The diagnosis may be made by isolating virus from blood or body fluids, by positive IgM antibody or by showing a fourfold rise in antibody titre. Early diagnosis is mainly based on direct detection of viral antigens or RNA.[40] Diagnosis can be confirmed by visualisation of characteristic viral particles by electron microscopy.

TREATMENT

Therapy is essentially supportive for a severe shock state. Haemorrhage is managed by replacement of blood, platelets and clotting factors as indicated. Ribavirin is useful in treating LF, Rift Valley fever and CCHF.[40] Ribavirin may reduce mortality by tenfold if treatment is begun within 6 days of onset. A 30 mg/kg i.v. loading dose is followed by 15 mg/kg q 6 h for 4 days and then 7.5 mg/kg q 8 h for another 6 days. Other treatment options are post-exposure vaccination.

PRECAUTIONS

In most countries these diseases must be notified immediately. In addition to universal blood and body fluid precautions, airborne isolation, including use of goggles, high-efficiency masks, a negative-pressure room with no air circulation, and positive-pressure filtered air respirators have all been recommended, as is surveillance of contacts. If applicable, to prevent further mosquito transmission, patients should be isolated in well-screened rooms sprayed with residual insecticides. Guidelines on infection control in the management of highly pathogenic infectious diseases have been published.[41]

Severe and Multiple Trauma

This page intentionally left blank

74

Severe and multiple trauma

James A Judson and Li C Hsee

Trauma can be defined as physical injury from mechanical energy. It is usually categorised as blunt or penetrating. In Western countries, severe blunt trauma is common, caused by road crashes, falls and, less frequently, blows and assault. Severe penetrating trauma, usually from stabbings and gunshots, is less common except in larger cities of the USA,[1,2] South Africa and war zones. Blunt trauma is often more difficult to treat than penetrating trauma. Assessment is more difficult, because injuries are frequently internal, multiple and not obvious initially. The risk of missing serious injuries can only be lessened by a systematic approach and repeated assessments.[3–5]

ASSESSMENT AND PRIORITIES

TRIAGE

An important first step is triage – sorting patients with acute life-threatening injuries and complications from those whose lives are not in danger. Depending on the complexity of injury, it is important to ensure resources are available for treatment. If institutional capacity is lacking, consider transferring the patient to an advanced trauma unit. The severity of total body injury is related to the number of separate injuries present, and to the severity of individual injuries. Assessment can be made either at the scene of injury or on arrival at hospital. As in any emergency, assessment, diagnosis and treatment need to be concurrent. There is limited time for detailed histories, examinations, investigations or well-considered diagnoses before starting emergency care.

RECOGNITION OF SEVERITY

Most patients with severe injury can be distinguished early by the following:

- *Depressed consciousness:* in the trauma patient, depressed consciousness can be related to brain injury, hypoxaemia, shock, alcohol or other ingested drugs, or precipitating neurological or cardiac events. Frequently, a combination of factors is present, and the precise extent of physical brain injury is not known initially. Initial treatment is in any case determined by the level of consciousness rather than its exact cause.
- *Breathing difficulty:* this is common in patients with trauma to the head, face, neck and chest. If rapid or distressed breathing is present then airway obstruction, laryngeal injury, pulmonary aspiration and lung or chest wall injury (especially pneumothorax and lung contusion) must be considered.
- *Signs of shock:* shock is almost always hypovolaemic from blood loss, but other types of shock occasionally occur in trauma (see below).

PRIORITIES

A trauma patient often has multiple problems requiring attention. Determining priorities is not always easy. In general, the priorities are to:

- *support life*: the patient is kept alive with resuscitative techniques, while the various injuries and complications are attended to
- *locate and control bleeding*, which may be varied (see below)
- *prevent brainstem compression* and spinal cord damage
- *diagnose and treat* all other injuries and complications.

BASIC TREATMENT PRINCIPLES

A systematic approach to managing severe and multiple trauma is important. Effective programmes developed by the American College of Surgeons are now well established.[6] A number of basic treatment principles apply to all severe trauma patients.

EMERGENCY ASSESSMENT (PRIMARY SURVEY)

The following must be recognised and treated before anything else:

- *A – Airway obstruction*: is suggested by noisy (or silent) breathing, with paradoxical chest movements and breathing distress, and inadequate airway protection from impaired gag reflexes in patients with depressed consciousness. Airway obstruction should be managed with cervical spine protection.

- *B – Breathing difficulty*: is suggested by tachypnoea, abnormal pattern of breathing, cyanosis or mental confusion.
- *C – Circulatory shock*: is manifested by cold peripheries with delayed capillary refill, rapid weak pulse or low blood pressure (see below).
- *D – Disability:* neurological status needs to be evaluated by checking the pupils and GCS. A decreased level of consciousness can be caused by poor cerebral perfusion, direct cerebral injuries, alcohol, recreational drugs and opiates.[6]
- *E – Exposure:* the patient needs to be exposed for examination, but at the same time hypothermia must be prevented and dignity preserved.[6]

OXYGEN AND VENTILATORY THERAPY

High-flow oxygen by mask is given to all trauma patients. Patients with severe trauma frequently require ventilatory support. A restless uncooperative patient should be anaesthetised and intubated under a rapid sequence induction to facilitate resuscitation.

BLOOD CROSSMATCH AND TESTS

Six units of red cells should be crossmatched urgently, but it is impossible to predict the amount of blood that will be required. Blood is concurrently sent for baseline haematological and biochemical tests, including blood ethanol level. Blood ethanol level is clinically useful in assessing individual patients with depressed consciousness, quite apart from epidemiological and preventive medicine,[7] and legal considerations.

FLUID RESUSCITATION

Resuscitation fluids are given (see below). If necessary, two or three large 14- or 16-gauge i.v. cannulae are inserted in upper limb, external jugular or femoral veins.

ANALGESIA

Analgesia is easily overlooked. Opioid agents should be titrated i.v., and not given i.m. or subcutaneously. Large doses may be needed.

URINE OUTPUT

A urinary catheter is inserted unless a ruptured urethra is suspected (because of blood at the urinary meatus, severe fractured pelvis or abnormal prostate position on rectal examination), in which case a urethrogram is indicated before catheterisation. Urine output monitoring is an important guide to resuscitation.

CLINICAL EVALUATION OF INJURIES (SECONDARY SURVEY)

Injuries are easily missed in an emergency, especially when one injury is obvious. A secondary, and even a tertiary, survey should be performed.[5] The back and the front of the patient should be examined. Special attention is paid to regions with external lacerations, contusions and abrasions. All body regions are examined systematically.

HEAD

Neurological observations are made. The ears and nose are inspected for cerebrospinal fluid and blood, and the scalp is examined thoroughly.

FACE

Bleeding into the airway should be excluded, and the face and jaws tested for abnormal mobility.

SPINE

A cervical spine fracture or dislocation is assumed in all patients with depressed consciousness until proved otherwise. Signs of spinal cord injury should be sought (e.g. warm dilated peripheries from loss of vasomotor tone, diaphragmatic breathing, paralysis, priapism and loss of anal tone). The thoracic and lumbar spine should be inspected and palpated.

THORAX

Fractured ribs in themselves are not usually life threatening, but haemothorax, pneumothorax, lung contusion and chest wall instability (flail chest) will require attention if present. Tension pneumothorax is a life-threatening emergency that needs to be detected and treated early. Less common but very serious injuries can occur to the heart and great vessels (see Ch. 77).

ABDOMEN

The spleen, liver and mesenteries are often damaged. Retroperitoneal haemorrhage is common. Injuries to the pancreas, duodenum and other hollow viscera are less frequent, and may be missed until signs of peritonitis occur. Renal injury with retroperitoneal haemorrhage is suggested by haematuria and loin pain (see Ch. 79).

PELVIS

Pelvic fractures may be difficult to detect clinically, especially in the unconscious patient. Blood loss may be massive, particularly with posterior fractures involving sacroiliac dislocation. Ruptured bladder and ruptured urethra may occur with anterior fractures.

EXTREMITIES

A litre or more of blood may be lost into a fractured femur. Long-bone fractures are more serious when they are open, comminuted or displaced, or if associated with nerve or arterial damage.

EXTERNAL

Contusions may be extensive and serious, especially in falls from heights, and may be overlooked if the victim's back is not examined. Road crash victims may sustain serious burns or abrasions.

SHOCK IN THE TRAUMA PATIENT

The earliest, most constant and reliable signs of shock are seen in the peripheral circulation. A patient with cold, pale peripheries has shock until proved otherwise. Tachycardia is not always present and hypotension is a late sign of shock. The commonest form of shock in trauma is hypovolaemic shock.

HYPOVOLAEMIC SHOCK

If the neck veins are empty, hypovolaemic shock should be inferred. Possible sites of blood loss causing shock are:

- *external loss*, which is obvious clinically from blood-soaked clothing and pooled blood
- *major fractures*, which are obvious clinically by deformity, swelling, crepitus, pain and tenderness (e.g. femurs) or seen on a plain X-ray (e.g. pelvis)
- *pleural cavity*, detected on urgent chest X-ray. Intrapleural drains will reveal the amount and rate of blood loss
- *peritoneal cavity*, detected by laparotomy, diagnostic peritoneal lavage, computed tomography (CT) scan or ultrasound. Clinical examination of the abdomen can be misleading when the patient is intoxicated, has depressed consciousness or has multiple injuries. A single clinical examination is of limited value; changes over time are more important
- *retroperitoneum*, detected at laparotomy or by CT scan, or inferred when all the above are negative, especially in the presence of pelvic or lumbar spine fracture.

CARDIOGENIC SHOCK

If the trauma patient with shock has distended neck veins, possible causes are tension pneumothorax, concurrent myocardial infarction, cardiac tamponade or myocardial contusion.

NEUROLOGICAL SHOCK

Patients with paraplegia or tetraplegia from spinal cord injury may have low blood pressure with warm dilated peripheries accompanied by lax anal tone and by priapism in the male (see Ch. 78). This is a diagnosis of exclusion and all causes of hypovolaemic shock (see above) must be sought.

SEPTIC SHOCK

Occasionally, patients with pulmonary aspiration may develop septic shock. This is unlikely to confuse the initial trauma assessment soon after injury, but may require consideration some hours or a day or two later.

ABDOMINAL ULTRASOUND

The non-invasive nature and increasing availability of FAST (focused assessment with sonography for trauma) scanning in emergency departments has made this modality attractive in trauma to detect haemoperitoneum and haemopericardium.

However:[8]

- it is operator dependent and needs to be performed by trained personnel
- it may have an unacceptably high false-negative rate
- there is a small but important false-positive rate for intra-abdominal bleeding
- it is unable to diagnose ruptured bowel
- it is not good for bleeding in the pelvis.

Its main usefulness is in the shocked patient, where a positive FAST indicates the need for immediate laparotomy without further investigation.[6,9,10]

DIAGNOSTIC PERITONEAL LAVAGE

Diagnostic peritoneal lavage (DPL) is indicated to diagnose intra-abdominal bleeding and sometimes bowel injury.

This is an invasive procedure that may make subsequent clinical abdominal examination difficult.[6,11]

Caution is needed with pregnancy, previous abdominal surgery or massive pelvic injury. Isotonic saline 1 L (or 10 mL/kg) is instilled into the peritoneal cavity, after drainage of the stomach and bladder. The presence of more than 10 mL frank blood on catheter aspiration necessitates immediate laparotomy; otherwise a lavage fluid specimen should be examined for red and white cell counts and amylase concentration. A red cell count over 100 000 per mm^3, white cell count over 500 per mm^3, or an increased amylase concentration suggests bleeding or viscus injury, and laparotomy should be undertaken immediately. These absolute figures are debatable, however, and lower values are accepted in penetrating trauma.[6,12,13]

CT ABDOMEN

Improved availability, reduced scanning times and better definition are increasingly favouring CT abdomen over DPL in patients who are sufficiently stable to tolerate the procedure safely. It needs to be performed quickly and safely, with gastric and i.v. contrast, and interpreted by radiologists experienced in trauma. Visualisation of abdominal and pelvic organs and haemorrhage is excellent.[14,15] Diaphragm, pancreas and hollow viscus injuries may be difficult to visualise on CT, but the presence of free fluid in the absence of solid organ injury raises suspicion of hollow viscus injury.[16]

FLUID RESUSCITATION

TYPES OF FLUIDS

Almost all patients who are hypotensive or noticeably vasoconstricted will need blood transfusion but, in general, transfusion of large quantities of blood is wasteful while bleeding is uncontrolled. Isotonic saline or a balanced salt solution should be the first fluid infused. Shocked patients may need 2–3 L in the first few minutes. One-litre bags or bottles and giving sets with in-line pumps should be used on all i.v. lines. If fluid resuscitation is likely to be extensive, warmed fluids and rapid infusion devices should be used. Albumin solutions (and probably other colloid resuscitation fluids) are contraindicated in trauma patients as the SAFE study conducted in ICU patients showed higher mortality in patients given albumin, in the predetermined trauma subgroup, particularly in those with traumatic brain injury.[17] By 20–30 minutes crossmatched red cells should be available. Uncrossmatched group O Rh-negative blood is occasionally indicated in the exsanguinating patient.

All resuscitation fluids have a high sodium concentration, similar to that of extracellular fluid. Glucose 5% and glucose–saline solutions are not effective resuscitation fluids. Few trauma patients actually require them in the first day.

THE EXSANGUINATING PATIENT

With exsanguination secondary to penetrating thoracic injury, there is a place for emergency room thoracotomy, but this approach has little place in blunt trauma.[18] The exsanguinating blunt trauma patient needs rapid intubation, volume resuscitation, bilateral intrapleural drains, chest and pelvic X-ray, and a rapid trip to the operating room if it seems likely that the bleeding is in the thorax or abdomen.

MASSIVE TRANSFUSION PROTOCOL

Coagulopathy is common in patients with haemorrhagic shock and can be made worse by fluid resuscitation. Many institutions will have a massive transfusion protocol (MTP) for exsanguinating patients. The principle of MTP is to increase plasma to platelet to red blood cells ratios during the resuscitation phase.[19] MTP is shown to improve outcome. Haemostatic agents such as tranexamic acid and factor VIIa are increasingly used as a part of MTP.[20,21]

PERMISSIVE HYPOTENSION

In penetrating trauma, there is some evidence that extensive fluid resuscitation prior to haemostasis may be detrimental, presumably because of higher blood pressure, displacement of blood clot and dilution of coagulation factors.[22,23]

In blunt trauma, there is no such evidence. Furthermore, it is not appropriate to generalise the evidence from penetrating trauma to blunt trauma because these two types of trauma are quite different. In penetrating trauma, the bleeding is often from single arteries without extensive tissue injury, and complete haemostasis can often be easily achieved. In contrast, in blunt trauma, the bleeding is often venous as well as arterial, with capillary oozing into the soft tissues, which may continue for hours. It can often not be completely controlled by operative surgery, interventional radiology or reduction and fixation of fractures. Accordingly, fluid resuscitation is an important part of the treatment of circulatory shock in blunt trauma (see section on Inadequate resuscitation). Nevertheless, fluid resuscitation must not be used as an excuse for delaying haemostasis in blunt trauma.

Furthermore, traumatic brain injury is often present in blunt trauma, which frequently involves several body regions. Hypotension is disastrous to an already injured brain, and must not be prolonged by underresuscitation (see Ch. 75, section on Traumatic brain injury – emergency treatment).[24–26]

DAMAGE CONTROL RESUSCITATION (DCR)

Damage control surgery was described some years ago as abbreviated surgery to stop bleeding and contamination, followed by a period of ICU care before further surgery, to try to arrest the lethal triad of acidosis, hypothermia and coagulopathy.[27] US military experience with combat patients is extending this concept to fluid resuscitation as well, with a tendency to give no (or only small amounts of) resuscitation fluids before haemostatic surgery. As such, DCR is seen to integrate permissive hypotension, haemostatic resuscitation, and damage control surgery.[28] Some enthusiasts are now injudiciously extending DCR to other types of trauma.[29] As mentioned above under permissive hypotension, great caution should be exercised before extending this concept to non-exsanguinating blunt trauma, particularly if a traumatic brain injury is present,[26] or if remote from a trauma centre.

URINE OUTPUT

Hourly urine output is a useful guide to resuscitation from shock. Minimal acceptable urine output is 0.5 mL/kg per hour, but 1–2 mL/kg per hour is more adequate. Furosemide has no place in initial resuscitation. Apart from adequate resuscitation, diuresis can be due to ethanol, mannitol, dopamine, nephrogenic or neurogenic diabetes insipidus, or non-oliguric renal failure. Polyuria may mask early recognition of acute renal failure.

INADEQUATE RESUSCITATION

Patients in shock have depleted interstitial fluid as well as circulating blood volume, and need trauma resuscitation fluid volumes greater than the actual volume of blood lost. With blunt injury, volume losses often continue for 24–48 hours. Prolonged shock from delayed

and inadequate resuscitation leads to renal failure, acute respiratory distress syndrome (ARDS), sepsis, disseminated intravascular coagulation (DIC) and multiple organ dysfunction.[30,31]

PULMONARY OEDEMA

Pulmonary oedema during resuscitation may be related to fluid overload, direct lung trauma, aspiration of gastric contents, pulmonary responses to non-thoracic trauma and reactions to resuscitation fluids. They can all cause leaky capillaries and produce non-cardiogenic pulmonary oedema.

RADIOLOGY FOR TRAUMA PATIENTS

Patients with depressed consciousness, breathing difficulties or unstable circulation should be X-rayed in the emergency department, and not sent to a radiology department remote from skilled resuscitation facilities. Conversely, extensive imaging examinations of shocked patients in the emergency department are unacceptable. Only three examinations should ever be requested in the emergency department.

CHEST

This is the only X-ray ever justified in an unresuscitated patient. A supine film is usually sufficient. An erect film is better for showing intrapleural air or fluid, ruptured diaphragm, free abdominal gas and for defining an abnormal mediastinum, but is often impractical in shock or suspected spinal injury. It can be done later if feasible. Tension pneumothorax is a clinical diagnosis and does not require a chest X-ray before insertion of an intercostal drain.

LATERAL CERVICAL SPINE

Lateral cervical spine X-ray in the severely injured patient is now largely replaced by CT. It is only an initial screening examination for cervical spine fractures and does not ‘clear’ the spine. With head or facial injuries, a cervical fracture should be assumed initially and a cervical collar applied.

PELVIS

Unexplained blood loss can be due to a missed pelvic fracture. A dislocated hip can be missed in multiple injuries. A pelvic X-ray is not needed in awake patients with no pelvic abnormalities.

OTHER RADIOLOGICAL INVESTIGATIONS

Other X-rays should be performed after adequate resuscitation in the radiology department, operating room or intensive care unit (ICU):

- *Skull*: plain skull X-rays are not useful and do not guide immediate treatment. An urgent CT scan of the brain is a more useful investigation.
- *Extremities*: X-rays of the extremities to assess bony injuries are not urgent unless there is vascular injury. Therefore, these films should not be taken in the emergency department, unless the patient is going directly to the operating room for fracture fixation.
- *Spine*: X-rays of thoracic or lumbosacral spine are seldom indicated in the emergency department.
- *Abdomen*: a plain abdominal X-ray is of limited value in the initial evaluation of trauma. It may be helpful in high-velocity penetrating injuries, such as gunshot wounds, to help determine trajectory.
- *CT abdomen*: this can be valuable to evaluate a patient who is haemodynamically sufficiently stable to tolerate the procedure safely (see above).
- *CT head*: this is vital in the treatment of traumatic brain injuries.
- *CT neck*: the most reliable way to exclude or delineate cervical spine injuries is by a CT neck scan,[4,32] which can conveniently be done when the patient is going to the CT scanner for other examinations.
- *CT thorax*: apart from diagnosis of aortic injury, CT thorax is of limited value in the trauma patient. Visualisation of thoracic structures is excellent, but it seldom discovers important undiagnosed injuries that affect patient treatment.[33] If aortic injury is suspected, multislice CT is the current definitive diagnostic test. The use of aortic stent grafts for this injury, in locations where this technology is available, means that CT is not only the best diagnostic test but also necessary for preoperative planning.[34] Aortography is no longer the definitive diagnostic test for traumatic aortic rupture.
- *Urethrography:* this is used when urethral injury is suspected. Properly done CT abdomen may well demonstrate bladder injury; otherwise *cystography* is used.
- *Interventional radiology*: percutaneous transcatheter embolisation is therapeutic rather than diagnostic. It can provide life-saving haemostasis in massive retroperitoneal haemorrhage associated with pelvic fracture.[35] The logistics of managing such haemodynamically unstable patients in the radiology department are formidable.

TRAUMATIC BRAIN INJURY (SEE CH. 75)

Injuries to the head region are common, but those requiring urgent cranial operations are less so. Traumatic brain injury may initially be obvious amongst multiple injuries, but may not be the most important injury. Conversely, traumatic brain injury may seem initially unimportant. Traumatic brain injury is a major determinant of outcome in critically injured patients.

EMERGENCY TREATMENT

Resuscitation measures, as in the emergency assessment (primary survey) section above, are undertaken. Victims with one or both dilated unreactive pupils, or

a rapidly deteriorating level of consciousness not due to hypoxia or shock, should be given mannitol 1 g/kg i.v. to relieve brainstem compression until definitive diagnosis and treatment can be arranged. However, mannitol should be given only if the patient has been adequately volume-resuscitated as it may add to hypovolaemia. In the ICU, concentrated salt is often preferred to mannitol because it is readily available and does not produce hypovolaemia.[36,37]

Shocked trauma patients with or without traumatic brain injuries require the same crystalloid resuscitation fluids. Treatment of shock and maintenance of cerebral perfusion are vital, as hypotension is disastrous to an already damaged brain.[24–26] Contrary to common belief, sodium-containing fluids are not inherently dangerous in traumatic brain injury. However, after adequate resuscitation further sodium administration is usually not indicated. Excessive (free) water is potentially dangerous, however, as it can lead to hypo-osmolar brain swelling.[38]

NEUROLOGICAL EVALUATION

Factors such as hypoxaemia, shock, alcohol, analgesics, anaesthetic agents, muscle relaxants and other drugs confound neurological signs. Clinical neurological evaluation includes the Glasgow Coma Scale (GCS)[39,40] and a search for lateralising signs.

CT scanning is indicated in all patients who will not obey verbal commands, especially if they are rendered neurologically inaccessible by sedative and relaxant agents. Lateralising motor or pupillary signs with a deteriorating level of consciousness are indications for immediate CT scanning (or, if unavailable, emergency burr holes). In an unstable patient, a laparotomy for intra-abdominal haemorrhage should take priority over a head CT scan.[41]

SEVERITY AND MORBIDITY OF TRAUMA

Severity of injury is measured by the Abbreviated Injury Scale (AIS), updated over the years, most recently in 2008.[42–44] AIS divides the body into six regions: head and neck, face, thorax, abdomen, pelvis and extremities, and external. Specific injuries in each body region are coded on a scale of 1 (minor), 2 (moderate), 3 (serious, not life threatening), 4 (severe, life threatening, survival probable), 5 (critical, survival uncertain) and 6 (unsurvivable). The AIS was designed for motor vehicle injuries, but has been validated for blunt and penetrating trauma. It can provide a basis for research, education, audit and allocation of resources.

Severity of trauma is related not just to the severity of individual injuries, but also to the combined effects of multiple injuries. Multiple injuries are graded by the Injury Severity Score (ISS), which is an empirical system based on the AIS grades for the three worst body regions.[45,46] ISS gives a score between 0 and 75 for total body injury; 16 or more indicates major trauma. Death with an ISS below 24 should be rare. Above an ISS of 25, there is a stepwise increase in mortality, with very high rates over 50.[47,48]

The AIS and ISS study mostly the anatomy of injury. Other factors influence trauma mortality and morbidity, including age, pre-existing health, degree of physiological derangement, standard of prehospital and early hospital care, and complications. Degree of physiological derangement can be measured by the Revised Trauma Score (RTS),[49] which is computed from the coded values of the GCS, systolic blood pressure and respiratory rate, usually at admission to the emergency department. The Trauma Score – Injury Severity Score (TRISS) is based on the RTS, ISS and patient age.[50] It correlates well with outcome, and has been used to compile survival norms for blunt and penetrating trauma.[47,48] Physiological scoring systems such as APACHE (Acute Physiology and Chronic Health Evaluation) do not work well for trauma patients (see Ch. 3).[51,52] Pre-injury illness (co-morbidity) has a profound effect on trauma outcome.[53]

Shock influences trauma mortality and morbidity. Complications of shock include renal failure, ARDS, sepsis, liver failure and multi-organ dysfunction.[30,31,54] Acute oliguric renal failure on the first day after trauma is now rare, but non-oliguric renal failure is often seen 2–4 days later, caused by the shock and delayed or inadequate resuscitation. It is often heralded by polyuria, which is misinterpreted as a sign of adequate resuscitation.

EPIDEMIOLOGY OF INJURIES

Only a minority of victims of severe trauma reach hospital alive.[55,56] The majority of deaths are immediate (within minutes) at the scene of injury. Some deaths are early (within hours) in the emergency department or the operating room, and a few are late (after days or weeks) and occur in the ICU or ward.[57] Those in the ICU are mostly from severe head injury within a few days and, less commonly, multi-organ dysfunction later.

Of trauma admissions to hospital, only a minority have severe or multiple trauma.[58] In order of frequency, life-threatening injuries involve the head, abdomen and chest (**Table 74.1**), and are often multiple. The hospital services that this small number of severely injured patients use out of proportion to their numbers are major surgery, intensive care, radiography and CT scanning.[58] Major trauma outcome studies in the USA,[47] the UK[48] and Australasia[59,60] offer valuable epidemiological data. The USA study found that the mortality of direct admissions is strongly related to serious head injury.

ORGANISATION OF TRAUMA CARE

Many of the problems of trauma care are organisational. Problems faced by health authorities are the

Table 74.1 Percentage of ICU trauma patients with grades of injury in different body regions

	AIS≥4	AIS 3	AIS 1 OR 2	AIS 0
Head and neck	63	9	9	19
Face	2	11	8	79
Thorax	10	17	7	66
Abdomen	17	6	2	75
Extremities	1	31	11	57
External	0	<1	63	37

Data on 5031 trauma patients (excluding burns) in the Department of Critical Care Medicine, Auckland City Hospital, 1988–2011. Abbreviated injury scale (AIS-80) codes: 0= no injury; 1=minor; 2=moderate; 3=serious; not life threatening; 4=severe; life threatening, survival probable; 5=critical; survival uncertain; 6=unsurvivable. In tertiary referral centres (like Auckland City Hospital) these figures will vary with the mix of local and referred patients.[60]

provision of advanced care at the scene of injury, rapid transportation to hospital, policies on which hospitals should receive trauma patients, systems for rapid evaluation and decision making in hospitals, and rapid, safe patient transfer between hospitals. If survival from major trauma is to be maximised then prehospital and hospital care must be coordinated.

Regionalisation of trauma care has become an accepted concept.[2,61] Trauma centres are designated hospitals that meet certain requirements. The main prerequisites are rapidly available experienced surgeons, anaesthetists and neurosurgeons, and a minimum number of patients seen annually for staff expertise. Regionalisation involves the concept of ambulances bypassing non-designated hospitals.[2] Helicopters are used increasingly to speed patient transportation.[62] Trauma teams are teams of surgeons and intensivists or anaesthetists who immediately attend the trauma victim on arrival at hospital.[2–4,54]

Trauma registries and databases are important tools in organising and improving trauma care. The UK major trauma outcome study[48] showed that the doctors in charge of resuscitation were often junior, delays in performing urgent operations were common, and the number of preventable deaths was significant. A hospital may not see enough trauma patients to justify a trauma team or supply adequate experience for its staff, and may not have all the facilities required by trauma patients. Transfer to a trauma hospital may be desirable, but geography and limited transport facilities may make such transfers hazardous.

In Western countries, trauma is a leading cause of death and disability under the age of 38 years.[47] Reduction of mortality and morbidity depends on public education, new legislations, on-site advanced care, rapid evacuation (see Ch. 4), hospital trauma expertise and coordination of services.[63,64]

Severe head injuries

John A Myburgh and Manoj K Saxena

Despite improvements in resuscitation and vital organ support, the management of patients with traumatic brain injury in the intensive care unit (ICU) presents a challenge to all members of the critical care team.

EPIDEMIOLOGY

Traumatic brain injury has been termed a 'silent global epidemic'. It accounts for up to 30% of all trauma-related deaths and is the leading cause of death in young males in developed countries. The impact of mechanisation in low- and middle-income countries has resulted in a substantial increase in the incidence and mortality from vehicular trauma.

In addition to this high mortality, the cost of survivors in these societies in emotional, social and financial terms is substantial as the effects of the original injury may persist for many years.

AETIOLOGY

Vehicular trauma, industrial accidents, falls and assaults account for the majority of head injury, with marked variations in patterns of injury across the world. In high-income countries such as Australia, the incidence of head injury due to vehicular trauma has significantly decreased due to technical improvements in vehicle design and safety and public health initiatives such as restraint devices, speed control and drink-driving legislation.[1]

DEMOGRAPHICS

The numbers of patients with traumatic brain injury presenting to hospitals vary widely in accordance with hospital admission policies and capabilities. Typical figures of all-cause head injury admissions in high-income countries range from 200 to 300 per 100 000 patients, with the majority of these managed in dedicated trauma centres.

Age- and gender-specific data typically show two peaks: one in the second and third decades, with a male : female ratio of 2 : 1, and the latter in the seventh to ninth decades with a more equal gender ratio.

PATTERNS OF INJURY

Traumatic brain injury represents a range of injury from mild head injury that may fully recover to severe injury associated with high mortality or high levels of disability.

Injury may be either blunt or penetrating, with the latter associated with a higher mortality.

Although the majority of head injuries (70–80%) are minor, a significant proportion of these patients have poor functional outcomes due to secondary brain insults and co-morbidities. Of the 20–30% who constitute moderate to severe head injury, approximately 10% of these are dead on admission whereas the remainder will usually require admission to the ICU for management in the first 7–10 days.

PATHOPHYSIOLOGY

Brain injury is a heterogeneous pathophysiological process.[2] It encompasses a spectrum of injury that includes the degree of brain damage at the time of injury (primary injury) in addition to insults that occur during the post-injury phase (secondary injury). These processes are depicted in **Figure 75.1**.

PRIMARY BRAIN INJURY

The severity of primary injury is determined by the degree of neuronal damage or death at the time of impact. This is the major determinant of outcome from traumatic brain injury.

Primary brain injuries include all types of injury to the brain parenchyma and vasculature. Primary injuries that are associated with adverse outcome include traumatic subarachnoid haemorrhage and non-evacuable mass lesions, particularly in critical parts of the brain such as the posterior fossa.

SECONDARY BRAIN INJURY

Secondary brain insults are characterised by a reduction in cerebral substrate availability and utilisation[3] (**Box 75.1**). Of these, hypotension (defined as a systolic blood pressure of <90 mmHg (11.97 kPa)), hypoxia (oxygen saturation <90% or Pa_{O_2}<50 mmHg (6.65 kPa)), hypoglycaemia, hyperpyrexia (temperature

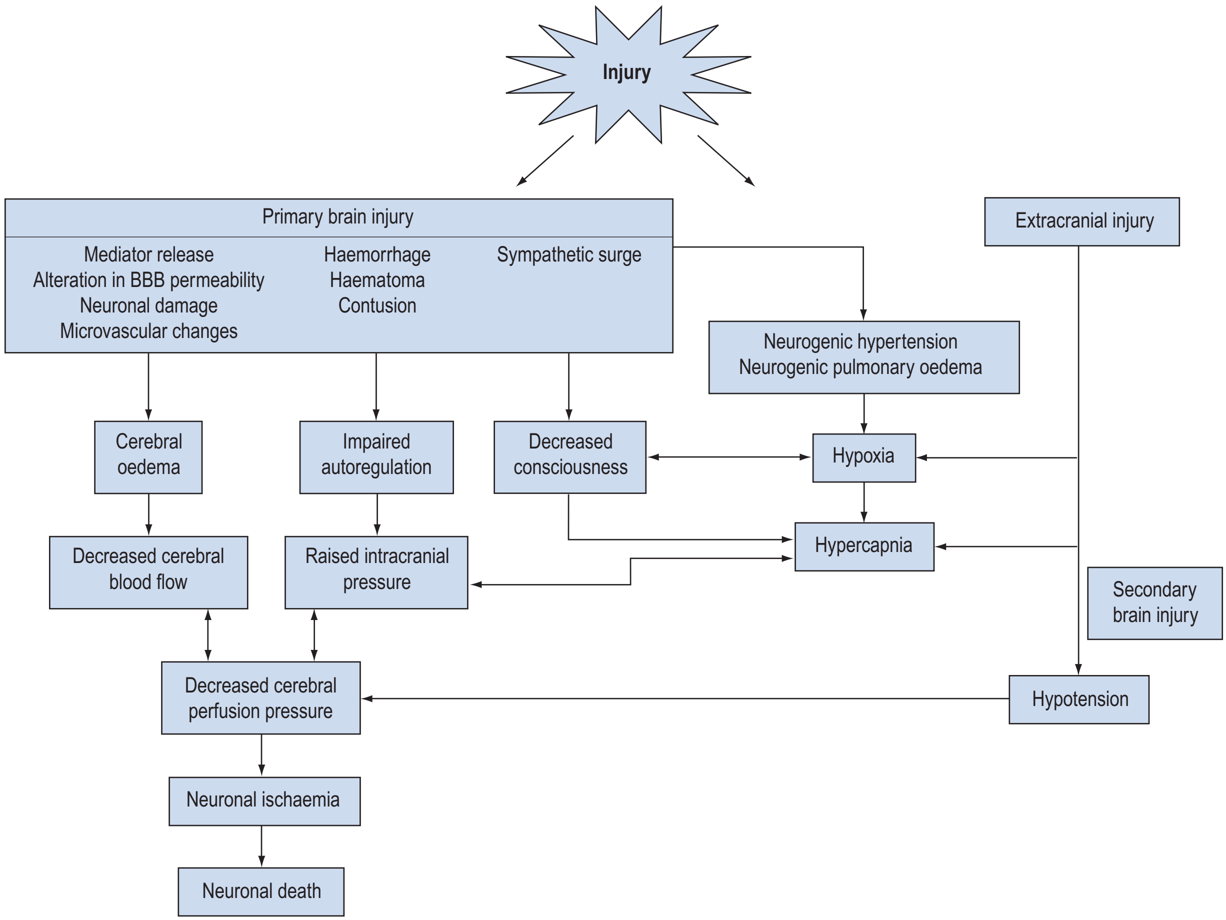

Figure 75.1 Pathophysiology of traumatic brain injury. BBB = blood brain barrier.

Box 75.1 Secondary brain insults following traumatic brain injury that are associated with increased morbidity and mortality

Systemic	Intracranial
Hypoxia	Seizure
Hypotension	Delayed haematoma
Hypocapnia	Subarachnoid haemorrhage
Hypercapnia	Vasospasm
Hyperthermia	Hydrocephalus
Hypoglycaemia	Neuroinfection
Hyperglycaemia	
Hyponatraemia	
Hypernatraemia	
Hyperosmolality	
Infection	

>39°C) and prolonged hypocapnia (Pa_{CO_2}<30 mmHg (3.99 kPa)) have been shown to independently worsen survival following traumatic brain injury.

Secondary insults may occur during initial resuscitation, transport both between and within hospitals, during anaesthesia and surgery, and in the ICU. These insults may initiate or propagate pathophysiological processes that may damage neurons already rendered susceptible by the primary injury.

INTRACRANIAL INFLAMMATION

As the brain is enclosed within the rigid skull and dura, small increases in intracranial volume result in sharp increases in intracranial pressure (Monroe–Kelly doctrine). Consequently, the brain is a poorly elastant organ with a limited capacity to accommodate pathological increases in intracranial pressure.

Traumatic brain injury invokes an inflammatory response characterised by the release of pro- and anti-inflammatory mediators. The consequence of this response is disruption and alteration in the permeability of the blood–brain barrier, glial swelling and alterations in regional and global cerebral blood flow. The extent of this inflammatory process is an important determinant of intracranial pressure that may persist for some time following injury. Furthermore, alteration

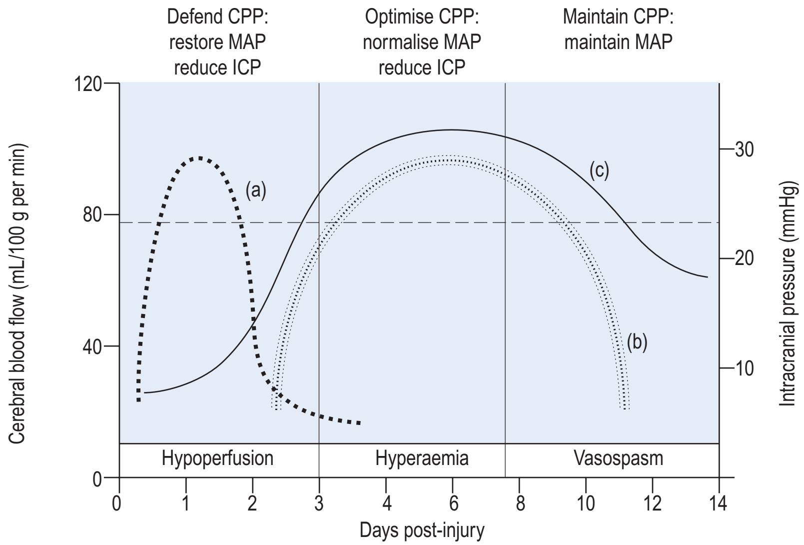

Figure 75.2 Conceptual changes in cerebral blood flow and intracranial pressure (ICP) over time following traumatic brain injury: (a) cytotoxic oedema; (b) vasogenic oedema; (c) cerebral blood flow. CPP=cerebral perfusion pressure, MAP=mean arterial pressure.

in blood–brain permeability may change the normal physiology of the cerebral circulation and alter the response to intravenous fluids, osmotic diuretics and vasoactive drugs.

CEREBRAL BLOOD FLOW AND AUTOREGULATION

Normally, cerebral blood flow is maintained at a constant rate in the presence of changing perfusion pressures by regional myogenic and metabolic autoregulation. These homeostatic mechanisms are impaired following head injury due to neuronal damage and intracranial inflammation. Distinct patterns of cerebral blood flow have been described following head injuries that have direct clinical relevance with regard to management[4] (**Fig. 75.2**).

THE HYPOPERFUSION PHASE

Cerebral blood flow is reduced by extrinsic and intrinsic mechanisms in the first 72 hours following injury, with resultant global and regional ischaemia. Because autoregulation is impaired during this period, cerebral blood flow is largely dependent on systemic blood pressure. Resultant neuronal ischaemia may result in 'cytotoxic' cerebral oedema and increased intracranial pressure.

THE HYPERAEMIC PHASE

Following the initial hypoperfusion phase, autoregulatory mechanisms may start to recover with improved cerebral blood flow.

During this phase, intracranial inflammation and/or effects of medical therapies directed at maintaining adequate cerebral perfusion pressure may result in cerebral hyperaemia and increased intracranial pressure. The consequences of hyperaemia, inflammation and altered blood–brain permeability may result in 'vasogenic' cerebral oedema.

This hyperaemic phase may persist for a variable period, up to 7–10 days post injury, and occurs in 25–30% patients.

THE VASOSPASTIC PHASE

In a small proportion of patients (10–15%), particularly those with severe primary and secondary injuries or those with significant traumatic subarachnoid haemorrhage, a vasospastic phase characterised by typical cerebral blood flow patterns may occur. This phase represents a complex of cerebral hypoperfusion due to arterial vasospasm, post-traumatic hypometabolism and impaired autoregulation.

RESUSCITATION

INITIAL ASSESSMENT

The resuscitation of head-injured patients should follow the principles outlined in the Advanced Trauma Life Support (ATLS®) guidelines for the early management of severe trauma.[5]

The initial emphasis is directed at assessing and controlling the airway, ensuring adequate oxygenation and ventilation, establishing adequate intravenous access and correcting hypotension. Neurological assessment and brain-specific treatment should follow only after cardiorespiratory stability has been established.

AIRWAY

All patients with severe head injury (traumatic coma), marked agitation or significant extracranial trauma require early oral endotracheal intubation.

Depending on the skill of the operator and available facilities, this should be performed using a rapid

sequence induction of anaesthesia with cricoid pressure and in-line immobilisation of the cervical spine.

All head-injured patients should be assumed to have a potential cervical spine injury, and should be immobilised in a rigid collar until that possibility is definitively excluded.

BREATHING (= VENTILATION)

Patients should be ventilated with 100% oxygen using 6–10 mL/kg tidal volumes until blood gas analysis is available.

Oxygenation should be maintained at least 80–100 mmHg (13 kPa) and the ventilator adjusted to achieve a normal arterial carbon dioxide tension (35–40 mmHg; 4.5–5.0 kPa).

Non-depolarising muscle relaxants and narcotics such as fentanyl may facilitate ventilation in the immediate post-intubation period in combative patients.

Empirical hyperventilation during initial resuscitation is not indicated.

CIRCULATION (= CONTROL OF SHOCK)

Prompt restoration of circulating blood volume and restoration of a euvolaemia is critical.

Early arterial monitoring for accurate measurement of mean arterial pressure and central venous catheter placement for providing a guide to volume replacement and administration of blood and drugs is essential. The placement of these lines must not delay volume resuscitation.

Blood transfusion should be commenced as soon as possible in actively bleeding patients with early administration of coagulation factors where appropriate.

Crystalloid, specifically normal saline, is recommended for fluid resuscitation of patients with traumatic brain injury.[6] Hypertonic saline may have a role as a small-volume resuscitation fluid in patients with traumatic brain injury, although there is no evidence of reduced mortality when used in the pre-hospital period.[7]

Vasoactive drugs such as epinephrine (adrenaline) or norepinephrine (noradrenaline) may be used to defend blood pressure once correction of hypovolaemia is under way. This may be necessary if sedatives or narcotics are co-administered.

DISABILITY (= NEUROLOGICAL ASSESSMENT)

Assessment of neurological function following injury is important to quantify the severity of traumatic brain injury and to provide prognostic information. This may be influenced by associated injuries, hypoxia, hypotension and/or drug or alcohol intoxication.

Recording the mechanism of injury is important, as high-velocity injuries are associated with a greater degree of neuronal damage. It is important to review ambulance and emergency personnel and records in order to obtain the most accurate information.

Level of consciousness

The ATLS® recommends an initial assessment during initial resuscitation based on the response to stimulation: Awake, Verbal, Pain, Unresponsive (AVPU). This provides a rapid and practical grading of function with severe head injuries defined as those who respond to pain only or who are unresponsive.

The Glasgow Coma Scale (GCS) has an established place in the management of traumatic brain injury and is the most widely accepted and understood scale.[8] Although originally described as a prognostic index, it provides an overall assessment of neurological function, derived from three parameters: eye opening, verbal response and motor response (**Table 75.1**).

The best responses in the GCS components should be recorded following cardiorespiratory resuscitation prior to surgical intervention. A GCS of 14–15 indicates a mild injury, 9–13 a moderate injury and 3–8 is classified as severe (traumatic coma). In severely injured patients or those who are intubated or with ocular or facial trauma, the motor response is the most useful.

Pupillary responses

Pupil size and reactivity are important when consciousness is impaired. Whilst not part of the GCS, pupillary function should always be assessed and recorded at the same time as the GCS, particularly prior to the administration of narcotics, sedatives or muscle relaxants.

Table 75.1 The Glasgow Coma Score[8] – the best response following non-surgical resuscitation is scored

BEST EYES OPEN SCORE		BEST VERBAL RESPONSE		BEST MOTOR RESPONSE	
Spontaneously	4	Orientated, adequate	5	Obeys spoken command	6
On spoken command	3	Disorientated, confused	4	Localised pain	5
To pain	2	Inappropriate words	3	Flexion withdrawal	4
No response	1	Incomprehensible	2	Abnormal flexion	3
		No response	1	Extension	2
		INTUBATED PATIENTS:		No response	1
		Appears able to converse	5		
		Questionable ability to converse	3		
		Unresponsive	1		

In the absence of traumatic mydriasis, abnormalities of pupil size and reactivity may indicate compression of the third cranial nerve, suggesting raised intracranial pressure or impending herniation, particularly when associated with lateralising motor signs and depressed consciousness.

Papilloedema is uncommon in the acute phase of head injuries.

Motor function

In addition to the motor response of the GCS, decerebrate or decorticate posturing, hemiparesis or lateralising signs, paraparesis and quadriparesis (given the high association with spinal injuries with traumatic brain injury) should be documented concurrently with the GCS and pupillary responses.

SECONDARY SURVEY

Once the initial assessment is complete and resuscitation under way, a thorough secondary survey adopting a 'top-to-toe' approach, as outlined in the ATLS®, is mandatory.

The principles outlined in the initial assessment form the basis for prioritising interventions in the secondary survey. Extracranial causes of hypoxia such as pulmonary contusion or haemo/pneumothorax must be excluded and promptly treated. Haemorrhage – both externally from fractures or lacerations and internally from major vascular disruption or visceral injuries – must be aggressively treated until circulatory stability is achieved. There is no place for 'permissive hypotension' in head-injured patients as has been advocated in selected cases of penetrating trauma.

Target mean arterial pressure should be estimated in the context of the patient's premorbid blood pressure. Higher pressures may be necessary in hypertensive or elderly patients. The early use of vasoactive drugs such as epinephrine or norepinephrine may be necessary to achieve this.

An approach of 'damage-control surgery' is recommended in patients with traumatic brain injury to minimise secondary insults.[9] In the initial 24–48 hours following injury, only life- or limb-threatening injuries should be addressed, following which patients should be transferred to the ICU for stabilisation and monitoring. Thereafter, semiurgent surgery such as fixation of closed fractures or delayed plastic repairs may be done.[10] Patients with severe traumatic brain injury undergoing prolonged emergency surgery should have intracranial pressure monitoring placed as soon as possible.

BRAIN-SPECIFIC RESUSCITATION

The place of interventions and therapies specifically directed at reducing intracranial pressure has been extensively reviewed in evidence-based guidelines for the management of severe head injury.[11]

HYPERVENTILATION

Ventilation-induced reductions in Pa_{CO_2} result in marked reductions in cerebral blood flow and consequently in intracranial pressure. However, as cerebral blood flow may be reduced during the initial period following injury, further reductions in cerebral perfusion will result if hyperventilation is used during this phase. Consequently, empirical hyperventilation is not indicated during initial resuscitation.

In the resuscitated head-injured patient with unequivocal clinical signs of raised intracranial pressure or impending tentorial herniation (pupillary dilatation, lateralising signs or a witnessed neurological deterioration), temporary hyperventilation is an option. Reductions of Pa_{CO_2} to levels ≤30 mmHg (4 kPa) may be considered prior to urgent imaging or surgery for evacuation of a mass lesion.[12]

OSMOTHERAPY

Osmotically active agents, such as mannitol, are administered to increase plasma osmolality in order to cause net efflux of fluid from areas of oedematous brain, with resultant reduction in intracranial pressure. An intact blood–brain barrier is necessary for this to occur. Following intravenous administration of mannitol, an immediate plasma-expanding effect that reduces haematocrit and viscosity ensues, which temporarily increases cerebral blood flow. Subsequent reductions in intracranial pressure probably result from restoration in cerebral perfusion pressure and rheological changes in cerebral blood flow rather than specific cerebral dehydration.

Osmotherapy is associated with a number of potentially adverse effects. Mannitol exerts an osmotic effect over a narrow range of plasma osmolality (290–330 mosm/L), above which theoretically beneficial effects may be negated, and induces an osmolal gap between measured and calculated osmolality. This gap may be increased by alcohol, which is frequently present in the acute period. Mannitol will enter the brain where the blood–brain barrier is damaged, thereby potentially increasing cerebral oedema by increasing brain osmolality. It is a potent osmotic diuretic that may compromise haemodynamic stability by inducing an inappropriate diuresis in a hypovolaemic patient.

Given the high risk with minimal benefit during resuscitation, the routine use of mannitol is not recommended in the absence of raised intracranial pressure.[13]

Similarly to hyperventilation, mannitol is considered as an option only in resuscitated patients with unequivocal signs of raised intracranial pressure prior to imaging or evacuation of a mass lesion. Although doses are frequently quoted as 0.25–1.0 g/kg, lower doses are equally as effective as higher doses in terms of improving cerebral perfusion and are associated with a lower incidence of side-effects.

Hypertonic saline (3% solution) exerts similar osmotic plasma-expanding effects to mannitol. These solutions do not exert an osmolal gap so serum sodium reflects serum osmolality allowing easier titration.[14]

EMERGENCY SURGICAL DECOMPRESSION ('BURR HOLES')

The advent of advanced in-field resuscitation, medical retrieval, imaging, teleradiology and telemedicine in high-income countries has largely superseded the need to perform urgent, undirected craniotomy in patients with traumatic brain injury. In most instances, patients are resuscitated, stabilised and imaged with CT scans prior to any surgical intervention. This usually involves transfer to a specialised trauma centre.

In remote communities or in low- and middle-income countries without immediate access to CT scanning, surgical evacuation may be life-saving in selected patients with a strong clinical probability of an expanding mass lesion such as an extradural or subdural haematoma. These include patients with low-velocity injuries to the temporal region with an associated skull fracture and developing lateralising neurological signs.

IMAGING

X-RAYS

Routine 'trauma series' of X-rays, namely chest, pelvis, skull and cervical spine, have been superseded by high-resolution, multislice computerised tomography (CT). In areas without immediate access to CT, X-rays should focus on identifying injuries or confirmation of placement of lines and tubes post resuscitation.

COMPUTED TOMOGRAPHY (CT) SCAN

CT scanning is now standard in all patients following traumatic brain injury. As CT scanning requires moving the patient to a radiological suite, this must be done only when initial assessment and resuscitation are complete and the patient is stable enough to be transported by appropriately trained and equipped personnel.

The following patients should undergo CT head scan following traumatic brain injury:

- all patients with a history of loss of consciousness or traumatic coma (GCS<8)
- combative patients where clinical assessment is masked by associated alcohol, drugs or extracranial injuries; these patients may require endotracheal intubation, sedation and ventilation to facilitate completion of CT scanning
- to exclude a cervical spine injury.[15]

The most important role of CT scanning is prompt detection of intracranial mass lesions such as extradural or subdural haematomas. Thereafter, the degree of brain injury may be quantified by radiological criteria (**Table 75.2** and **Fig. 75.3a**).[16,17]

Table 75.2 Classification of CT scan appearance following traumatic brain injury[16]*

CATEGORY	DEFINITION
DI I (diffuse injury)	No visible intracranial pathology seen on CT scan
DI II (diffuse injury)	Cisterns are present with midline shift 0–5 mm and/or: Lesion densities present No high- or mixed-density lesion >25 mm May include bony fragments and foreign bodies
DI III (swelling)	Cisterns are compressed or absent with midline shift 0–5 mm *No* high- or mixed-density lesion >25 mm
DI IV (shift)	Midline shift >5 mm *No* high- or mixed-density lesion >25 mm
Evacuated mass lesion	Any lesion surgically evacuated
Non-evacuated mass lesion	High- or mixed-density lesion >25 mm, not surgically evacuated

*An example is shown in Figure 75.3a.

These criteria are important for providing an index of injury severity, providing criteria for intracranial pressure monitoring, comparing the progression of injuries with subsequent scans and providing an index for prognosis. Examples of typical injuries appear in **Figure 75.3**.

The presence of traumatic subarachnoid haemorrhage should be recorded. This is an important index of severity of injury and is relevant for prognostication.[18]

MAGNETIC RESONANCE IMAGING (MRI)

Magnetic resonance imaging provides accurate details of parenchymal damage, specifically small collections and non-haemorrhagic contusions. The information provided is not significantly better than that obtained from CT scanning to warrant routine use of MRI in the acute phase of injury.

In patients when a major intracranial vascular injury is suspected, such as carotid artery dissection where the patient's clinical condition is not consistent with the CT findings (e.g. a dense hemiparesis in the absence of a mass lesion), magnetic resonance angiography (MRA) or direct cerebral angiography is indicated.

MRI has an emerging role in prognostication at a later stage in management.[19]

INTER-HOSPITAL TRANSFER

All severely head-injured patients should be managed at a specialised neurotrauma centre in close collaboration with intensive care physicians and neurosurgeons. This may involve intra- or inter-hospital transportation. Appropriately skilled and equipped personnel should do this only once resuscitation, stabilisation and initial imaging are completed.

A full primary and secondary survey and review of all documentation and investigation is required following transfer to a secondary or tertiary centre.

(b)

INTENSIVE CARE MANAGEMENT

There is no standard or uniform method of managing traumatic brain injury in the ICU. Most practices are determined by local preferences and experience, caseload and resources. The Brain Trauma Foundation of the American Association of Neurological Surgeons has published evidence-based management guidelines for the management of severe brain injury.[11]

Following initial resuscitation, good intensive care management forms the basis of head injury management and is regarded as a continuum of care. This takes priority over brain-specific therapies, which to date remain inconclusive in their efficacy.

HAEMODYNAMIC MANAGEMENT

Monitoring

Accurate measurement of systemic blood pressure is essential and should be measured via an arterial catheter referenced to the aortic root. A large artery such as the femoral artery should be considered in haemodynamically unstable patients as radial or dorsalis pedis arterial catheters may underestimate systemic pressure in shocked patients. Given the importance of maintaining adequate systemic blood pressure, non-invasive measurement of blood pressure is not recommended during the acute phase of monitoring.

Therapy should be titrated to mean arterial pressure in accordance with the patient's premorbid blood pressure – i.e. in older patients, higher mean arterial pressure (e.g. 70–80 mmHg; 9.31–10.64 kPa) may be necessary.[3]

Volume status should be assessed using clinical criteria including pulse rate, right atrial and mean arterial pressure, urine output serum sodium and osmolality, urea and creatinine.

Pulmonary artery catheterisation for the measurement of cardiac output and pulmonary artery pressures is rarely indicated in head-injured patients and is not recommended.

Fluid management

The attainment of euvolaemia is essential throughout intensive care management; both dehydration and fluid overload should be avoided.

Normal saline is the resuscitation fluid of choice for patients with traumatic brain injury. The use of albumin is associated with increased mortality due to increased intracranial pressure; whether this applies to other colloids is unknown but, on current evidence, resuscitation with colloids should be avoided.[6] Equally, hypotonic crystalloids such as compounded sodium lactate (Ringer's lactate or Hartmann's solution) should be avoided.

Maintenance fluids should be restricted to a minimum and directed at maintaining normal serum sodium (140–145 mmol/L) and osmolality (290–310 mosmol/L). As a general principle, glucose-containing solutions are not recommended; however, these may be required if patients become hyperosmolal (>320 mosm/L).

Vasoactive therapy

Catecholamines such as epinephrine, norepinephrine or dopamine are frequently used to augment mean arterial pressure to attain an adequate cerebral perfusion pressure. These should be commenced once volume resuscitation is actively under way. The early use of vasoactive drugs is increasingly being advocated during resuscitation as an important strategy during the hypoperfusion phase.[20]

There are no conclusive trials to recommend one vasoactive drug over another or combination of drugs. Epinephrine, norepinephrine and dopamine are equally effective in augmenting cerebral perfusion pressure.[21] The degree by which these agents directly affect the cerebral circulation following head injury is unknown, although there is some evidence suggesting that dopamine has both direct cerebrovascular and adverse neuroendocrine effects.[21]

Norepinephrine is currently regarded as the initial agent of choice for patients with traumatic brain injury in doses titrated to achieve a target mean arterial or cerebral perfusion pressure. Epinephrine is widely used, particularly in low-income countries, but may be associated with transient metabolic side-effects such as hyperlactataemia and hyperglycaemia, which may confound assessment of the adequacy of circulatory and metabolic resuscitation.[22]

Doses may range widely between and within patients to attain a target cerebral perfusion pressure. However, excessive doses of catecholamines (i.e. >40 μg/min) should be avoided, particularly after 72 hours after injury when lower cerebral perfusion pressure targets (i.e. 40–60 mmHg) may be appropriate. At all times, other causes of hypotension such as dehydration, sedatives, bleeding and sepsis must to be excluded.

Vasopressin is commonly used as a catecholamine-sparing agent or as a primary vasopressor, but its role in traumatic brain injury has not been established and is not recommended.

Neurogenic hypertension

Neurogenic hypertension is common in the latter phases following injury (>5 days) and is usually centrally mediated. It may be associated with ECG changes and/or supraventricular arrhythmias. It is usually self-limiting and correlates with the severity of injury, although a proportion may require long-term therapy. Treatment depends on the severity of the problem: beta blockers or centrally acting agents such as clonidine are usually effective; vasodilators are contraindicated.

RESPIRATORY THERAPY

Monitoring

Continuous measurement of arterial oxygen saturation is essential.

Continuous measurement of end-tidal carbon dioxide is frequently performed in ventilated patients, although the reliability is questionable and should be intermittently checked with arterial blood gases to maintain normocapnia.

Monitoring of ventilatory parameters should be consistent with standard approaches and includes measurement of tidal volumes, respiratory rates, and inspiratory and expiratory airway pressures.

Ventilation

The majority of patients with severe head injury will require mechanical ventilation to ensure adequate oxygenation and to maintain normocapnia (36–40 mmHg; 4.8–5.3 kPa).

The principles of optimal ventilation, humidification and weaning are addressed elsewhere. Strategies such as 'permissive hypercapnia' that are advocated for selected patients with acute lung injury or acute respiratory distress syndrome do not have a role in head-injured patients owing to the requirement to maintain normocapnia.

Positive end-expiratory pressure (PEEP) is recommended at low levels (5–10 cmH_2O) to maintain functional residual capacity and oxygenation. Higher levels may compromise systemic blood pressure, particularly in hypovolaemic patients, and should be used with caution. High levels of PEEP (>15 cmH_2O) may compromise cerebral venous return but adverse effects on intracranial pressure are uncommon.

Weaning from ventilation should commence once intracranial pathology has stabilised – that is, resolution of cerebral oedema on CT scan and control of intracranial hypertension.

Trials of extubation should be carefully considered so that subsequent hypoxic episodes do not occur, as these are potent secondary insults.

Patients with slow recovery of adequate consciousness should be considered for early tracheostomy, either percutaneously or surgically.

Neurogenic pulmonary oedema

This is a dramatic clinical syndrome that occurs in some patients with severe head injury and correlates with severity of injury. The underlying pathophysiological process is complex, but is primarily related to centrally mediated sympathetic overactivity. It is characterised by sudden onset of clinical pulmonary oedema, hypoxia, low filling pressures, poor lung compliance and bilateral lung infiltrates, usually within 2–8 hours following injury.

The process is usually self-limiting and treatment is primarily supportive, aimed at ensuring adequate oxygenation and ventilation. This usually requires endotracheal intubation and mechanical ventilation with the administration of PEEP. Ablation of sympathetic overactivity is effectively done with adequate sedation; beta blockade is usually unnecessary. Diuretics are effective, particularly if patients have received substantive fluid resuscitation, and must be titrated against the volume status of the patient.

The development of pulmonary oedema in patients with cardiac disease should be regarded as cardiogenic until proven otherwise.

Nosocomial pneumonia

Head-injured patients who require prolonged ventilation are at increased risk of nosocomial pneumonia. Risk factors include barbiturate and hypothermia therapy. Diagnosis and treatment are discussed elsewhere.

SEDATION, ANALGESIA AND MUSCLE RELAXANTS

There are no standards for sedation and analgesia in head-injured patients – protocols will depend on local preferences and resources. The level of sedation and analgesia required for head-injured patients depends on the degree of traumatic coma, haemodynamic stability, intracranial pressure and systemic effects of the head injury itself.[23]

During the initial resuscitation phase, sedation should be titrated to cause the least effect on systemic blood pressure. During this period, short-acting narcotics such as fentanyl are useful particularly if patients have associated extracranial injuries. These agents have relatively little adverse effect on haemodynamics and have the additional benefit of tempering the systemic sympathetic surges that frequently occur after injury. As narcotics affect pupillary responses, these must be documented before administration. Short-term muscle relaxants such as vecuronium are useful to control combative patients following intubation, ventilation and sedation.

During the intensive care phase, the requirements for sedation are different. Sedation should be titrated to have the patient sedated as lightly as possible to allow clinical assessment of neurological function and to facilitate mechanical ventilation. The level of sedation will depend on haemodynamic stability and the degree of intracranial pressure. Infusions of narcotics and benzodiazepines (e.g. morphine and midazolam) are useful in providing moderate to deep levels of sedation and are effective in controlling surges of intracranial pressure. However, these agents may accumulate, resulting in a delay in return of consciousness or, if used for prolonged periods, may be associated with an emergent delirium state.

The use of propofol as a sole sedating agent has become popular. It provides deep levels of sedation, which is effective in controlling systemic sympathetic swings and rises in intracranial pressure. It is rapidly reversible on cessation allowing prompt assessment of neurological status and does not accumulate. In addition, pupillary responses are not directly affected. Propofol should be used with caution in haemodynamically unstable patients, however, as it is a potent negative inotrope. The prolonged use of propofol is associated with tachyphylaxis and significant caloric loading from the lipid vector. Concerns have been raised about myocardial depression and sudden cardiac death, particularly if large doses are administered.[24]

The routine use of muscle relaxants is not recommended either to facilitate sedation or to control raised intracranial pressure. The prolonged use of these agents is associated with adverse outcome in traumatic brain injury and prolonged use of non-depolarising muscle relaxants is associated with polyneuromyopathies.

BODY POSITION AND PHYSIOTHERAPY

Patients should be nursed at 30–45° head elevation to facilitate ventilation, improve oxygenation and reduce the risk of aspiration. The head should be kept in a neutral position.

Physiotherapy has an important role in the removal of lung secretions, prevention of contractures and venous thrombosis. Patients with raised intracranial pressure may require boluses of sedation before chest physiotherapy to prevent acute rises in intracranial pressure.

METABOLIC MANAGEMENT

Routine measurement of biochemistry is essential with the aim of keeping all parameters within normal limits, in particular serum sodium levels.

Hyperglycaemia is common following severe head injury and is usually centrally mediated and transient. Blood sugar levels should be maintained within normal limits with insulin infusions, between 8.0–10.0 mmol/L; hypoglycaemia should be avoided.

Core temperature should be routinely monitored as hyperthermia has been identified as a cause of secondary injury. Normothermia (core temperature at 37°C) is recommended.

NUTRITION

The caloric needs of head-injured patients must be addressed as soon as possible following resuscitation. Early enteral feeding is recommended.[25]

Placement of a nasogastric and/or enteral feeding tubes in head-injured patients is usually via the oral route until an anterior cranial fossa (fractured cribriform plate) is excluded.

STRESS ULCER PROPHYLAXIS

The incidence of gastric erosions and 'stress ulceration' has markedly decreased with better resuscitation and early enteral feeding. Head-injured patients are at no more risk than other critically ill patients for developing stress ulceration.

H_2 antagonists or proton pump inhibitors should be used in ventilated patients until enteral feeding is established, following which they may be ceased.

Patients with a previous history of peptic ulceration should remain on proton pump inhibitors for the duration of the intensive care stay.

THROMBOPROPHYLAXIS

Head-injured patients, particularly those requiring prolonged ventilation and sedation or with extracranial injuries, are at increased risk for developing thromboembolism. The use of anticoagulants such as fractionated or low-molecular-weight heparins is contraindicated in patients with clinically significant intracranial haemorrhage. Consequently, the role of thromboprophylactic agents in head injury is difficult and there are no standards for their use.[26]

As a general rule, anticoagulants should not be used in head-injured patients with any evidence of destructive intracranial pathology or haemorrhage until there is resolution of these processes on CT scan.

Non-pharmacological methods of thromboprophylaxis such as elastic stockings or pneumatic calf compressors are of unproven effectiveness, but provide a reasonable alternative. Frequent surveillance using Doppler ultrasound of the iliofemoral veins in high-risk patients, such as those with pelvic fractures, should be considered. Patients who develop deep-vein thromboses and who cannot be anticoagulated should be considered for inferior vena caval filters. The use of anticoagulants in head-injured patients with proven pulmonary embolism will depend on the relative risk to the patient's life.

ANTIBIOTICS

These should be used sparingly and in accordance with accepted microbiological principles. Prophylactic antibiotics should be prescribed only to cover insertion of intracranial pressure monitors and are not recommended for basal skull fractures. Frequent cultures of leaking or draining cerebrospinal fluid should be taken and infection treated specifically.[27]

BRAIN-SPECIFIC MONITORING

The most accurate assessment of brain function following traumatic brain injury is a full clinical neurological examination in the absence of drugs or sedatives. However, this is often not possible for the majority of head-injured patients managed in the ICU.

Ideally, neuromonitoring should provide accurate and integrated information about intracranial pressure, patterns and adequacy of cerebral perfusion, and an assessment of cerebral function. No such monitor exists, although each of these parameters may be monitored in various ways with variable levels of accuracy and clinical utility.

CLINICAL ASSESSMENT

Regular assessments of GCS, pupillary signs and motor responses should be made and recorded in the ICU flow chart. Concomitant sedation may influence the level of consciousness and this should be recorded. Initially, these assessments are recorded hourly, but this may change as patients become more stable.

A witnessed deterioration in GCS, especially the motor response, or the development of new lateralising signs should be regarded as life-threatening intracranial hypertension or tentorial herniation until proven otherwise.

INTRACRANIAL PRESSURE MONITORING

The recognition that raised intracranial pressure is associated with adverse outcome led to the measurement of this parameter in order to quantify the degree of injury and to assess the response to treatments directed at reducing intracranial pressure.

Indications

The Brain Trauma Foundation guidelines[28] recommend intracranial pressure monitoring in patients with

traumatic coma (severe head injury: GCS=8 following non-surgical resuscitation) with any of the following:

- abnormal CT scan
- diffuse injury II–IV (see Table 75.2) or
- high- or mixed-density lesions >25 mm^3
- normal CT scan with two or more of the following features:
  - age >40 years
  - unilateral or bilateral motor posturing
  - significant extracranial trauma with systolic hypotension (<90 mmHg (11.97 kPa)).

Coagulopathy is a relative contraindication to intracranial pressure monitoring.

Methods

Measurement of intracranial pressure[29] with an intraventricular catheter is the most accurate and clinically useful method. It has the advantages of zero calibration and drainage of cerebrospinal fluid drainage. Disadvantages include technical difficulty with insertion, particularly in patients with cerebral oedema and compression of the lateral ventricles, and an increased incidence of infection.

Solid-state systems such as fibreoptic (e.g. Camino®) or strain gauge tipped catheters (e.g. Codman®) may be placed intraparenchymally or intraventricularly. These systems transduce intracranial pressure to provide high-fidelity waveforms. They are small calibre and, although requiring a small craniotomy (burr hole) for insertion, may be inserted at the bedside. Disadvantages include inability to perform zero calibration after insertion and baseline drift that may be significant after 5 days.

Fluid-filled subdural catheters have been used for many years. However, these are no longer recommended owing to the development of more accurate solid-state systems. Subdural pressures do not accurately reflect global intracranial pressure, particularly in the presence of a craniectomy. Pressure readings may also be affected by local clot formation within the catheter.

Thresholds

Measurements are used to calculate cerebral perfusion pressure: mean arterial pressure minus intracranial pressure. For this calculation, both measurements should be referenced to the external auditory meatus (equivalent to the circle of Willis).

Intracranial pressure monitoring should be continued until the patient can be assessed clinically and intracranial pressure has stabilised (<20–25 cmH_2O). This occurs in the majority of patients within 7 days. Patients with refractory intracranial hypertension may require monitoring for longer periods, although this may be complicated by drift (with solid-state systems), infection (with intraventricular catheters) or occlusion (subdural catheters). In this situation, intracranial pressure monitors may need to be replaced or removed and patients assessed by serial CT scan or clinically.[30]

CEREBRAL BLOOD FLOW MONITORING

Currently, there is no method of routinely measuring cerebral blood flow at the bedside. Technological advances such as mapping with labelled xenon under computed tomography and laser Doppler flowmetry provide useful imaging of regional and cerebral blood flow. However, these techniques are intermittent, labour-intensive and limited to research-based units.

A number of qualitative measurement techniques are available that provide an indirect assessment of cerebral blood flow and have a limited and undefined role in routine management.

Jugular bulb oximetry

Measurement of oxygen saturation in the jugular bulb by the retrograde placement of a fibreoptic catheter provides an indirect assessment of cerebral perfusion. Low jugular venous saturations (<55%) may be indicative of cerebral hypoperfusion whereas high levels of jugular venous saturation (>85%) may be indicative of cerebral hyperaemia or inadequate neuronal metabolism, such as occurs during the hyperaemic phase or during the evolution of brain death. Both low and high jugular venous saturations are associated with adverse outcomes.[31]

There are insufficient data to provide evidence-based indications for the routine use of jugular bulb oximetry. Its use is limited to experienced units when an index of cerebral blood flow may be required during adjunctive therapies in patients with intracranial hypertension – for example, augmentation with catecholamines, barbiturate coma, hyperventilation or hypothermia.[32]

Transcranial Doppler

Transcranial Doppler ultrasonography with a 2-MHz pulsed Doppler probe allows non-invasive, intermittent or continuous assessment of the velocity of blood flow through large cerebral vessels. Insonation through a naturally occurring acoustic window such as the transtemporal approach allows insonation of the anterior, middle and posterior cerebral arteries, terminal internal carotid artery and anterior and posterior communicating arteries. However, the technique is operator-dependent and there may be significant variations in velocity patterns during the course of the injury. Measured indices of flow include systolic, mean and diastolic flow velocities.

Distinct patterns associated with normal, hyperaemic, vasospastic and absent flow are recognised. Derived indices such as the Gosling pulsatility index (systolic/diastolic difference divided by the mean velocity) and Lindegaard ratio (between middle cerebral artery to extracranial internal carotid artery) may assist in differentiating these flow patterns.

Despite an increasing use of transcranial Doppler to diagnose post-traumatic hyperaemia and vasospasm, there are insufficient data to provide evidence-based indications for its routine use.[33]

CEREBRAL FUNCTION AND METABOLISM

Electroencephalography

Electroencephalography has been used for many years to assess seizure activity that may be masked by sedatives or muscle relaxants and to provide an objective estimate of the degree of electrical neuronal depression with barbiturate therapy. Although seizures may not be clinically apparent in a proportion of patients, and may constitute an important secondary insult, the accuracy and reliability of electroencephalography in ICU is questionable owing to outside electrical interference from monitors and ventilators.[34]

The development of bispectral index (BIS monitoring) as a measurement of depth of anaesthesia has led to the suggestion that this may be an alternative to the use of electroencephalography with barbiturate or sedative therapy in traumatic brain injury. Nevertheless, bispectral index has not been validated in this context and cannot be recommended as a titration end-point.[35]

Evoked potentials

Measurement of evoked potentials, assessing the integrity of sensory and motor pathways, may provide diagnostic and prognostic information; however, because of the complexity of the technique it is not recommended for general use. The reliance on one variable, such as evoked potentials, to predict outcome from traumatic brain injury is not recommended.[36]

Neuronal function

Research developments in microprobe technology have resulted in specific electrodes that may be placed into the brain parenchyma to measure brain oxygen, pH, lactate and carbon dioxide tensions. These may be individual electrodes or combined with other sensors such as pressure monitors to form multimodal tissue monitors.[32]

Cerebral microdialysis is a technique that measures brain extracellular fluid metabolites. Dialysate is obtained through a microdialysis catheter inserted through the same burr hole as an intracranial pressure monitor to measure concentration and fluxes of markers of intracranial inflammation (e.g. lactate, pyruvate and purines).

Although these systems provide highly specific information about the biochemical milieu of focal areas of brain tissue, their clinical utility is limited to research centres.

BRAIN INJURY SURVEILLANCE

Serial assessment of the anatomical injury is an important part of monitoring head injury. This is done by serial CT scanning at frequent intervals depending on the neurological status of the patient.

Any patient who develops an unexplained neurological deterioration or significant validated deviation of monitored parameters should have a CT scan so that new or delayed intracranial mass lesions are identified.

CT scans should be assessed and scored according to the classification outlined in Table 75.2. The progression or resolution of axonal injury, cerebral oedema, contusion and haemorrhages should be recorded. However, as CT scanning requires transport of the patient to a radiology suite, this should be done only by experienced personnel, when the patient is stable.

BRAIN-SPECIFIC THERAPY

Treatment options directed at ameliorating brain injury are limited. Despite intensive research into defining the pathobiological processes in primary injury, studies analysing therapies designed to modulate intracranial inflammation have not been successful. These include aminosteroids, calcium channel blockade and *N*-methyl-D-aspartic acid antagonists.

Brain-specific or 'targeted' therapy is directed at maintaining cerebral perfusion pressure and minimising intracranial pressure. Although there is an inherent relationship between these two principles, priorities are different depending on the time course of the underlying injury. This is important as strategies directed at one may have adverse effects on the other (see Fig. 75.2).

DEFENCE OF CEREBRAL PERFUSION PRESSURE

The Brain Trauma Foundation guidelines recommend a range of cerebral perfusion pressure of 60 mmHg (7.98 kPa).[37]

This requires a change from a 'set and forget' philosophy to one of 'titration against time' in order to prescribe desirable therapeutic targets.

Hypoperfusion phase (0–72 hours)

Cerebral hypoperfusion is present in the majority of patients with severe head injury (GCS=8). During this phase, there is an imperative to maintain cerebral perfusion pressure by supporting systemic haemodynamic function.

During this period, a cerebral perfusion pressure of at least 60 mmHg (7.98 kPa) is recommended. In addition to reduced cerebral blood flow, intracranial pressure may be increased by mass lesions or 'cytotoxic' cerebral oedema.

During this phase, medical therapies directed at raised intracranial pressure such as osmotherapy or hyperventilation should be used only if cerebral perfusion pressure is maintained at an appropriate level and the patient is adequately monitored.

Assessment of adequacy of the response to augmentation of cerebral perfusion pressure is made by

intracranial pressure trends, CT scan appearance and, where possible, neurological assessment. If patients appear to have stabilised, sedation may be reduced with the aim of extubation.

Hyperaemic phase (3–7 days)

Approximately 25–30% of patients will develop clinical signs of cerebral hyperaemia, characterised by increased intracranial pressure and persistent cerebral oedema on CT scan. This may occur due to vasogenic cerebral oedema caused by intracranial inflammation or in patients who require increasing doses of catecholamines (e.g. >40 μg/min of epinephrine or norepinephrine) to attain a target cerebral perfusion pressure.

In this context, a target cerebral perfusion pressure target of 40–60 mmHg (5.32–7.98 kPa) is recommended.

If patients continue to have raised intracranial pressure, strategies directed at reducing intracranial pressure should be considered.

REDUCTION OF INTRACRANIAL PRESSURE

In the absence of intracranial mass lesions, raised intracranial pressure is usually an indicator of severity of the underlying injury and represents exhausted intracranial elastance.

The most effective methods of reducing raised intracranial pressure are mechanical interventions such as removal of mass lesions, drainage of cerebrospinal fluid or decompressive craniectomy.

A number of medical strategies directed at reducing intracranial pressure have been used for many years. Despite widespread use and firmly held beliefs, there is little evidence to support the routine use of these therapies.[38]

Intracranial pressure should be maintained at <20–25 cmH_2O. Trends of intracranial pressure are equally as important and should be assessed within the context of cerebral perfusion pressure and the methods used to defend it.[30]

Surgical evacuation of mass lesions

The prompt detection and evacuation of mass lesions causing raised intracranial pressure is the most effective method of relieving intracranial hypertension. Although the majority of these lesions will be present immediately after injury and will be treated during the resuscitative phase, approximately 10% of patients will develop delayed intracranial haematomas. These are detected by sudden unexplained rises in intracranial pressure or by CT scan surveillance.

Cerebrospinal fluid drainage

Drainage of cerebrospinal fluid through an intraventricular catheter is an effective method of reducing intracranial pressure. If present, these catheters should be placed 5–10 cm above the head and opened for drainage every 1–4 hours.

Decompressive craniectomy

Wide, bilateral, frontoparietal craniectomies are highly effective in reducing intracranial pressure and have mainly been used in patients with refractory intracranial hypertension without evacuable mass lesions.

However, a large randomised-controlled trial of early decompressive craniectomy in patients with diffuse traumatic brain injury and early intracranial hypertension demonstrated an increase in unfavourable neurological outcome in survivors.[39] The role of decompressive craniectomy is now questioned in these patients.

Osmotherapy

The rationale and role of osmotherapy using mannitol or hypertonic solution are addressed above (in the section 'Brain-specific resuscitation'). These same principles also apply during intensive care management.

Mannitol or hypertonic saline should be used only in patients with validated intracranial hypertension who are euvolaemic, haemodynamically stable, with a serum osmolality <320 mosm/L.

There is no evidence that osmotherapy or induced dehydration improves outcome or is more effective in cytotoxic than vasogenic cerebral oedema.[13]

Hyperventilation

The role of hyperventilation during intensive care management is limited to the indications outlined in the section 'Brain-specific resuscitation'.

The routine prolonged use of hyperventilation in head-injured patients is associated with a worse outcome than patients ventilated to normocapnia. This is probably due to reduction of cerebral blood flow and secondary brain ischaemia.

Current evidence-based guidelines do not recommend the use of routine hyperventilation.[12]

Hypothermia

Induced hypothermia has been used for many years to reduce cerebral metabolism and thereby raised intracranial pressure. A theoretical benefit exists in experimental models where hypothermia is induced immediately following injury with prompt reduction in raised intracranial pressure. However, these benefits have not translated into improved outcomes in a number of clinical trials.[40]

Induced hypothermia (to temperatures of 30–33°C) is associated with prolonged ventilation and increased susceptibility to nosocomial infection, and may also be associated with increased morbidity and mortality in head-injured patients.

Currently, hypothermia is regarded as a 'second tier' option in patients with refractory intracranial hypertension but, on current evidence, cannot be recommended.[41]

Barbiturate coma

The role of barbiturates in traumatic brain injury is similar to hypothermia. Despite experimental evidence that barbiturates reduce cerebral metabolism and reduce intracranial pressure, no definitive studies have shown a benefit in clinical trials. Barbiturates have invariably been used in patients with refractory intracranial hypertension where a positive outcome was unlikely, making interpretation of these trials difficult.

Barbiturates may cause hypotension and reduce cerebral blood flow, potentially exacerbating secondary insults in patients with cerebral oligaemia. Prolonged use of barbiturates will delay awakening and predispose the patient to nosocomial infection.

Barbiturates are a 'second-tier' option in patients with refractory intracranial hypertension and are not recommended on current evidence.[23]

Steroids

Steroids have been advocated for many years to ameliorate intracranial inflammation, thereby reducing intracranial pressure. A large international study has provided conclusive evidence that high doses of steroids are associated with adverse outcomes in traumatic brain injury, and therefore have no place in management.[42,43]

CEREBRAL VASOSPASM

Post-traumatic cerebral vasospasm occurs in approximately 10–15% of patients. It is associated with a high morbidity and mortality. It is frequently present in patients with traumatic subarachnoid haemorrhage and is a marker of severity of injury, although the true incidence of clinically significant vasospasm is uncertain.

Treatment options remain limited. Calcium antagonists, such as nimodipine, have not been shown to be effective in traumatic subarachnoid haemorrhage. Strategies that have been used in aneurysmal subarachnoid haemorrhage such as 'triple H' therapy (induced hypertension, hypervolaemia and haemodilution) or chemical angioplasty have not been evaluated in traumatic subarachnoid haemorrhage and are not recommended.

SEIZURE PROPHYLAXIS

Seizures are infrequent following traumatic brain injury and usually present at the time of injury. These should be treated with anticonvulsants (e.g. diazepam, midazolam) when they occur. Subsequent prophylaxis with phenytoin is recommended only in patients with destructive parenchymal lesions on CT scan and should be continued for 10 days following injury. Short-term seizure prophylaxis does not prevent late-onset post-traumatic epilepsy.[44]

OUTCOME AND PROGNOSIS

Patient factors that determine outcome from traumatic brain injury include severity of primary and secondary injuries, traumatic coma (GCS<8), age >60 years and co-morbidities. Prediction of outcome is difficult as significant functional improvements, particularly in young patients, may occur over time.

There are patients in whom the prognosis is clearly very poor or hopeless. A proportion of these patients will become brain dead and may be considered for organ donation. In other patients, it may be appropriate to withdraw active treatment. This increasingly complex process requires time, careful consideration and consensus with all members of the healthcare team and relatives.

Outcomes from traumatic brain injury are difficult to quantify. Although mortality is an easy end-point to measure, functional outcome is an equally important measurement as the effects of traumatic brain injury on psychosocial recovery and duration of rehabilitation often take extended periods of time.

Faciomaxillary and upper-airway injuries

Cyrus Edibam and Hayley Robinson

MAXILLOFACIAL INJURIES

Blunt or penetrating faciomaxillary injuries may be isolated or part of multisystem trauma. Life-threatening associated injuries occur in 6.2% of patients with facial injuries and commonly include head, cervical spine and chest injury.[1] Life-threatening airway haemorrhage and airway obstruction are challenging issues and require skilled airway management to prevent adverse outcomes. This chapter outlines the basic anatomy, pathology, complications and common pitfalls in the emergency management of maxillofacial and upper-airway trauma.

EPIDEMIOLOGY

Maxillofacial trauma occurs most frequently in the 20–25-years age group and occurs three to five times more often in males than in females. Blunt injury mechanisms account for nearly 98% of all maxillofacial injuries.[2] Motor vehicle trauma accounts for nearly three-quarters of blunt injuries, the remainder being due to falls, physical assault, contact sports and industrial accidents. In some areas, legislative changes and preventative measures involving drink–driving, seatbelt and airbag use have seen a reduction in the incidence of motor-vehicle-related maxillofacial injury.[3] However, others have seen a large increase owing to alcohol and interpersonal violence.[4] In multiple trauma patients with an Injury Severity Score (ISS)>15, maxillofacial injury occurs in up to 16%, with a corresponding mortality rate of 10.5%.[2]

ANATOMICAL ASPECTS

Fractures, haemorrhage, soft-tissue damage and oedema are the commonest manifestations of blunt facial trauma. The severity of facial injury is directly related to the velocity of force applied. Common maxillofacial fractures involve the midface (71.5%), mandible (24.3%) and frontal bone (4.2%).[5]

MANDIBULAR FRACTURES

The mandible is a unique horseshoe-shaped bone that is tubular and weakest where the cortices are thinnest. Most fractures occur at vulnerable points, regardless of the point of impact.[6] Common sites of weakness include the condylar area, followed by the symphyseal and parasymphyseal area, and then the angle. Multiple fractures are common (64%),[6] with body of mandible fractures often being accompanied by fractures of the opposite angle or neck due to transmitted forces. Mandibular fragments are often distracted owing to the action of the lower jaw muscles. Respiratory obstruction may occur after bilateral mandibular angle or body fractures due to the posterior displacement of the tongue – the 'Andy Gump' fracture.[7]

MIDFACIAL FRACTURES

The bones of the middle third of the face are relatively thin and poorly reinforced. Fracture dislocations occur through the bones and suture lines and the facial skeleton acts as a compressible energy-absorbing mass that gives on impact. The series of compartments (nasal cavity, paranasal sinuses and orbits) within the bony framework collapse progressively, absorbing energy and protecting the brain, spinal cord and other vital structures.[8] Multiple complex facial fractures usually result and isolated facial bone fractures are rare. Le Fort described three great lines of weakness in the facial skeleton and subsequently derived the Le Fort fracture classification[9] **(Fig. 76.1)**. Le Fort fractures are perpendicular to the three main vertical buttresses of the facial skeleton – the nasomaxillary, zygomaticomaxillary and pterygomaxillary 'pillars'. Such fractures usually occur with mixed patterns as impact to the face is rarely centred (e.g. right hemifacial Le Fort I and left hemifacial Le Fort II). Airway obstruction may occur from posterior movement of the soft palate against the tongue and the posterior pharyngeal wall. Oral secretions, blood, bone and tooth debris and pharyngeal wall haematomas may worsen airway compromise.

LE FORT I (ALSO KNOWN AS GUERIN'S FRACTURE)

This fracture involves only the maxilla at the level of the nasal fossa. It follows a horizontal plane at the level of the nose. The fracture separates the palate from the remainder of the facial skeleton (i.e. palate–facial disjunction) and is usually caused by direct low-maxillary blows or by a lateral blow to the maxilla.

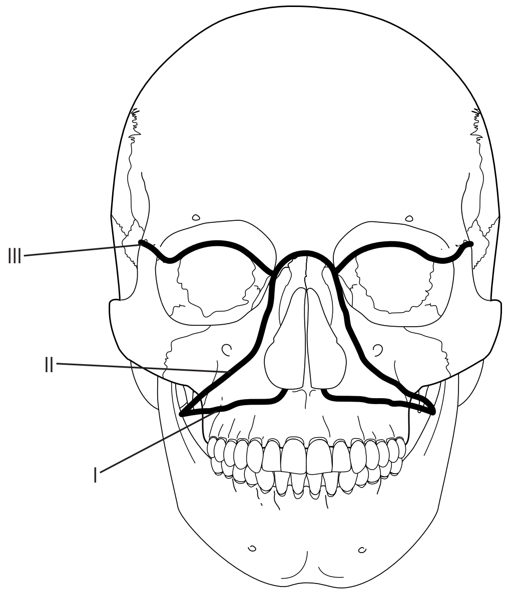

Figure 76.1 Le Fort classification of facial fractures.

LE FORT II

This is the most common midface fracture. The maxilla, nasal bones and medial aspect of the orbit are involved, which results in a freely mobile, pyramidal-shaped portion of the maxilla (i.e. pyramidal disjunction). The fracture line extends from the lower nasal bridge through the medial wall of the orbit, and crosses the zygomaticomaxillary process. It is caused by direct blows to the mid-alveolar area, or by lateral impacts and inferior blows to the mandible when the mouth is closed.

LE FORT III

This is known as craniofacial disjunction because the fracture line runs parallel to the base of the skull, separating the midfacial skeleton from the cranium. The fracture extends through the upper nasal bridge and most of the orbit and across the zygomatic arch. It involves the ethmoid bone, and thus may transect the cribriform plate at the base of the skull.[10,11] These fractures result from superiorly directed blows to the nasal bones.[11]

TEMPOROMANDIBULAR JOINT (TMJ)

Mechanical TMJ impairment may result from condylar or zygomatic arch fractures and can prevent jaw opening even after muscle relaxants have been administered.

ZYGOMATIC, ORBITAL AND NASAL FRACTURES

Zygomatic fractures account for 20% of all facial bone fractures. Its attachments to the maxilla, frontal and temporal bones are vulnerable and may be disrupted. When the zygoma is displaced, disruption of the lateral wall and floor of the orbit may ensue. Orbital injury is commonly associated with midface trauma. The severity of injury in the orbital region varies from oedema and ecchymosis of the periosteal soft tissue to subconjunctival haemorrhage[12] and loss of visual acuity or ocular rupture. Facial fractures are associated with visual loss and blinding in 0.7–10% of patients.[13–15] The blinding mechanism is usually associated with globe perforation rather than optic nerve injury. Orbital blowout fractures occur when pressure that is directly applied to the eye is hydraulically transmitted via the globe to the interior bony structures. The weaker inferior orbital wall usually fractures, causing enophthalmos, diplopia, impaired eye movement and infraorbital hypoaesthesia. Nasal fractures are common, with epistaxis and septal haematoma being the prime concerns.

SOFT-TISSUE INJURIES

Abrasions, contusions, lacerations to the tongue, palate, pharynx, cheek, eyelids, nasolacrimal duct, ear, parotid gland and facial nerve can occur. Oedema evolving over 24–48 hours can be massive and cause gross distortion of soft-tissue structures. Patency of an initially unobstructed airway may become compromised during this period.

HAEMORRHAGE

Haemorrhage following blunt maxillofacial injury is extremely common. Life-threatening bleeding is rare. Various series have reported the incidence to be between 1.25 and 11%.[12–14] Most severe haemorrhage is associated with midfacial fractures, although soft-tissue lacerations alone can cause significant blood loss. Swallowing of large quantities of blood may conceal haemorrhage and predispose to vomiting and aspiration.[15]

The origin of bleeding in facial trauma is complicated, as the vascular supply is derived from both the internal and external carotid arteries, with anastomoses occurring between them as well as between both halves of the face. The internal maxillary artery, especially the intraosseous branches, is the main source of bleeding in facial injury because the artery passes within the common Le Fort fracture borders.[16] The comminuted nature of maxillary fractures makes the detection of an exact site of vessel damage nearly impossible.[16] Branches of the internal carotid artery such as the lacrimal and zygomatic branches, as well as the anterior and posterior ethmoidal arteries, may contribute to bleeding.

ASSOCIATED INJURIES

More than half of all patients with maxillofacial injuries will have other injuries and these are listed below.

BASILAR SKULL FRACTURE

The anterior cranial fossa is often involved in craniofacial injuries. Fractures involving the frontal bone,

frontal sinus, nasoethmoid complex, or fronto-orbital complex result in bone defects in the skull base and can cause dural tears with resultant leakage of cerebrospinal fluid (CSF). CSF fistulae occur in 10–30% of basilar skull fractures.[17] The clinical finding of CSF rhinorrhoea represents only the site of exiting CSF and is not diagnostic for anterior cranial fossa lesions. The origin may be from a temporal bone fracture, because CSF from the middle ear discharges into the nose via the Eustachian tube. A middle cranial fossa defect can produce rhinorrhoea through the sphenoid sinus. The vast majority of fistulae present within 1 week of injury. Meningitis in patients with midface fractures is uncommon, despite the fact that approximately 25% develop CSF leaks.[18]

Pulsating exophthalmos and the presence of an orbital bruit may lead to the diagnosis of a carotido-cavernous fistula, which may develop following fractures involving the skull base and orbit.

HEAD AND CERVICAL SPINE INJURY

The incidence of head injury in those with maxillofacial trauma has been variably reported to be from 15% for severe head injury, increasing to 80% if all grades of head injuries are included.[14,19,20] Cervical spine injury has been reported in up to 11% of patients. The prevalence of cervical spine fracture with mandibular injury is 6.5%[21] and is attributed to forces exerted directly or indirectly from the facial skeleton to the neck. C1/C2 and C5–C7 are at particular risk.

The association between maxillofacial and cervical spine injury depends on the mechanism of injury. Falls and motor vehicle accident victims are more likely to have cervical injury than are sporting or personal assault victims.

OTHER INJURIES

Thoracic trauma (9–40%), abdominal trauma (5–40%) and limb fractures (30%) are other common coexistent injuries.[19,22] Traumatic injury of the internal carotid artery following maxillofacial trauma occurs in less than 0.5% of patients presenting with blunt maxillofacial injury.[23] It is often associated with mandible fractures or laterally displaced midface fractures (LeFort II and III[24]) and is recognised when a patient develops an unexplained neurological deficit, most often hemiplegia, subsequent to trauma or surgery of the head, face or neck. Assessment of the carotid circulation by CT angiography is a useful investigation if carotid injury is suspected.

ASSESSMENT OF INJURY

The obvious priorities are airway management and control of haemorrhage and identification of other life-threatening injuries. These are discussed later in detail. Once the patient is stable, formal assessment of the facial injuries can proceed.

HISTORY

Evaluation of facial fractures begins with a history of the injury. The mechanism of injury is important in order to assess the likelihood of other injuries.

EXAMINATION

Physical examination includes inspection of the deformity, presence of enophthalmos, asymmetry, dental malocclusion, nasal septal deviation or haematoma, CSF rhinorrhoea and the extent of jaw opening. Other signs associated with basal skull fracture should also be noted (haemotympanum, Battle's sign, raccoon eyes). Tenderness and mobility on bimanual palpation of the alveolar process and the infraorbital rim or frontozygomatic suture indicates the presence of a complex midfacial fracture. Naso-orbito-ethmoid instability can also be established by bimanual palpation. Visual acuity (in the conscious patient), corneal integrity and pupillary reflexes as well as eye movements (failure of upward movements in orbital blowout fracture) should be assessed early and thoroughly. Facial nerve function should also be assessed if possible. The presence of a bruit over the orbit may indicate a carotido-cavernous fistula.

INVESTIGATION

CT scanning, especially with three-dimensional reconstruction, is the preferred and most accurate method of imaging.[25] In addition to bony distortion, fluid in the paranasal sinuses, optic nerve integrity and soft-tissue distortion, the brain, upper cervical spine and other body areas can be visualised concurrently. Other investigations such as colour Doppler ultrasound studies, CT angiography or standard angiography of the great vessels in the neck may be required in cases of possible carotid dissection or carotid-cavernous fistulae. Nasal discharge should be tested for β_2-transferrin to confirm the presence of a CSF fistula.[26]

AIRWAY MANAGEMENT

Airway management in maxillofacial injury is potentially complex owing to multiple concurrent compromising factors (**Table 76.1**).

IMMEDIATE PRIORITIES

- Assess and monitor for signs of airway obstruction whilst maintaining cervical spine precautions
- Clear airway, assist respiration
- Definitive airway intervention.

An initially unobstructed airway may become compromised as swelling and oedema can progress in the initial hours after injury. Careful close monitoring in an intensive care unit (ICU) or high-dependency unit (HDU) is essential. Maintaining the head-up position and the use of humidified oxygen may lessen the likelihood of later airway compromise. Sudden obstruction may occur

Table 76.1 Airway problems in maxillofacial trauma

GENERAL PROBLEMS	MANAGEMENT
Haemorrhage/debris Impaired laryngoscopy Aspiration risk from blood swallowing Clot inhalation/obstruction Teeth, bone fragments	Suction, volume replacement Head down Definitive control of haemorrhage (see text)
Oedema soft-tissue haemotomas Increases over 48 hours Mask fit can be poor	Monitor airway closely Head up 30° Maintain spontaneous ventilation during airway Manipulation; laryngeal mask ventilation
SPECIFIC PROBLEMS	
Bilateral mandibular body/angle fractures Posterior displacement of tongue	Anterior traction on tongue or jaw, towel clip or suture through tongue and elevate
TMJ impairment from mandibular condyle and or zygomatic arch fracture Mouth opening limited	Nasotracheal intubation (blind/fibreoptic) or surgical airway may be required (see text)
Midfacial fracture Mask seal poor Soft palate collapses against pharynx	Anterior traction on mobile segment
Basilar skull Nasotracheal intubation contraindicated Pneumocephalus from mask ventilation	Avoid nasal intubation
Cervical spine injury	Orotracheal intubation with in-line stabilisation; fibreoptic intubation; surgical airway

with clot dislodgement and inhalation. Signs of partial obstruction include noisy breathing, stridor, intercostal or supraclavicular recession and restlessness.

Occasionally, patients may assume positions that lessen airway obstruction (e.g. sitting forward or even prone). Simple measures such as suction and clearing the airway and insertion of an oropharyngeal airway may suffice.

In midfacial injuries, anterior digital traction on the mobile mid-segment may relieve obstruction. In bilateral mandibular fractures of the angle or body, a towel clip or suture through the tongue may allow anterior traction on the unsupported tongue and relieve obstruction.

Bag and mask ventilation may be difficult owing to distorted anatomy, and this should be borne in mind when a decision to intubate is made. Failure of these simple manoeuvres necessitates definitive airway management

TECHNIQUES (FIG. 76.2)

Facilities to perform a surgical airway must be available prior to elective intubation. The chosen technique for securing the airway depends on the presence of airway obstruction and the likelihood of difficult direct laryngoscopy (extent of jaw opening, gross anatomical distortion and swelling, operator experience). In a combative patient, or if urgent intubation is necessary, a rapid sequence induction can be used if difficulty in direct laryngoscopy is not anticipated. If direct laryngoscopy is likely to be difficult or impossible, spontaneous respiration must be maintained and intubation carried out under local anaesthesia.

Analgesia can be achieved with a combination of sprayed or nebulised lignocaine (4%) to the posterior pharynx as well as a transcricoid injection of 2–4 mL lignocaine (2%). Adjunctive superior laryngeal and glossopharyngeal nerve blocks can be used.[27, 28] The orotracheal route for intubation is the route of choice in the presence of basal skull fracture.

If cervical spine injury is present or suspected, in-line stabilisation is mandatory. A variety of intubation techniques can be used – for example, direct laryngoscopy, awake fibreoptic-guided laryngoscopy, video laryngoscopy as well as retrograde intubation techniques.[29] The operator should use the technique with which he/she is most comfortable. Excessive bleeding or debris may render fibreoptic techniques difficult.

Failure to intubate and ventilate in the presence of airway obstruction necessitates the passage of an appropriate-sized laryngeal mask. If ventilation is not possible with a laryngeal mask in situ then emergency cricothyroidotomy should be performed. Formal tracheostomy may be required in those likely to need prolonged ventilatory support (e.g. multiple facial fractures combined with a head injury) and is best

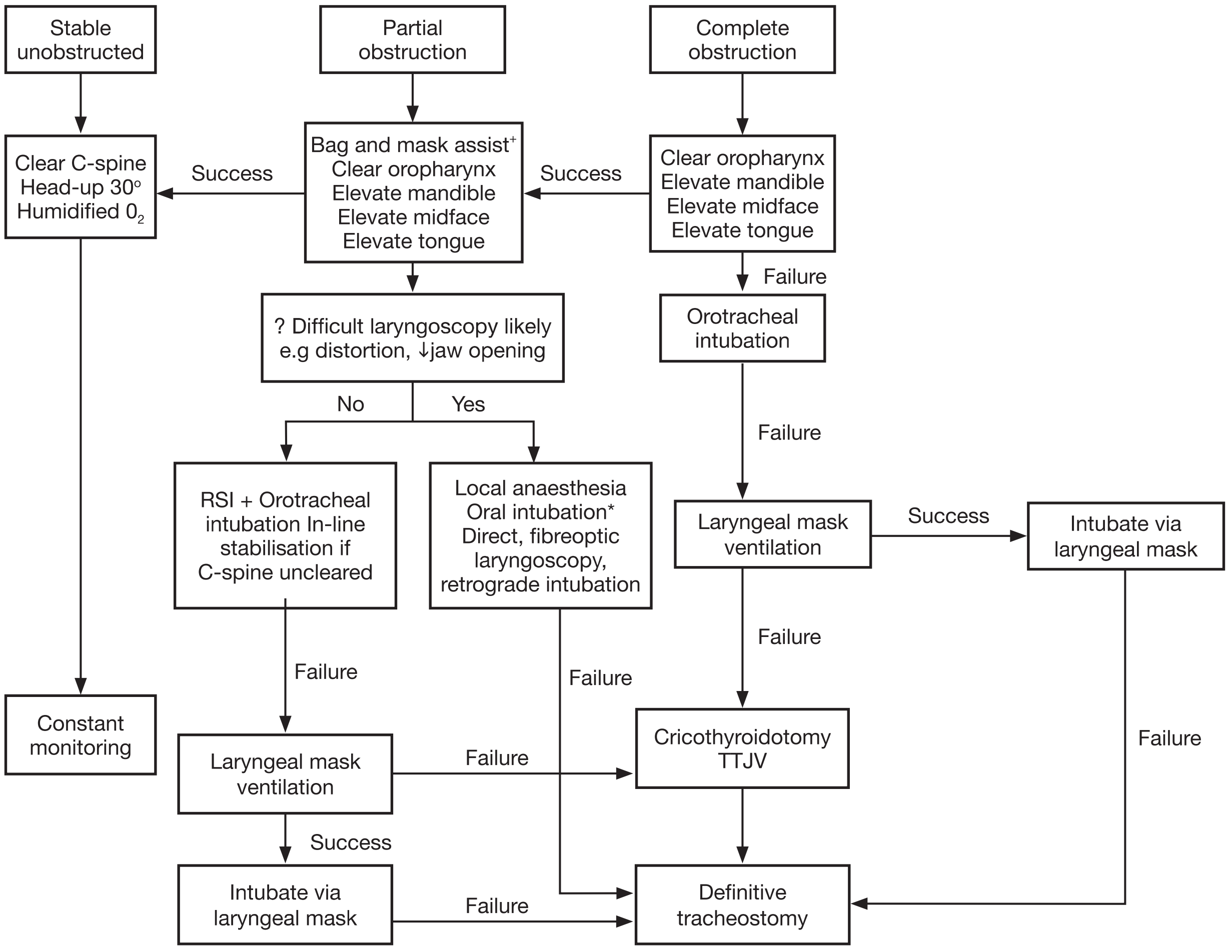

Figure 76.2 An airway management algorithm for maxillofacial trauma. C-spine=cervical spine; RSI=rapid sequence induction; TTJV=transtracheal jet ventilation. +Mask seal may be poor. *Nasotracheal route contraindicated in basilar skull fracture.

performed as a semi-elective procedure in the operating room.[16]

MANAGEMENT OF HAEMORRHAGE

Topical vasoconstrictors may not be effective with ongoing nasal haemorrhage. Anterior or posterior nasopharyngeal packs are sometimes effective at reducing blood loss. Foley catheters passed into the posterior nasopharynx with the balloons filled with air may stem blood loss, especially if anterior traction is applied in mild to moderate haemorrhage.[30] Angiographic embolisation has an increasing role as first-line approach for life-threatening intractable bleeding for blunt and penetrating trauma, with a success rate of greater than 85%.[30] Plastic or maxillofacial surgical opinion should always be sought early on regarding the appropriateness of angiographic versus operative intervention for persistent haemorrhage. Operative intervention includes reduction and stabilisation of fractures and direct ligation of bleeding vessels. External carotid ligation has failed to show consistent efficacy.

DEFINITIVE MANAGEMENT

Definitive surgery is generally delayed 4–10 days to allow swelling to subside. The timing of surgery may be further delayed if a severe head injury coexists. Early surgery may be warranted if orbital injury with optic nerve compromise is present. The use of high-dose steroids in optic nerve compression is controversial and no good data exist regarding its efficacy.[16] Irrigation and debridement of open wounds, closure of facial lacerations and removal of foreign bodies must be undertaken as soon as is practicable, preferably within 24 hours.

The use of prophylactic antibiotics for CSF leak is debateable and local protocols should be followed. The timing of operative intervention is still under discussion but the recent trend is for conservative management due to high rate of spontaneous closure, with lumbar drain

insertion for leakage lasting longer than 5– 7 days and endoscopic or surgical closure for those that persist.[31] Appropriate tetanus prophylaxis must be given.

The use of modern internal fixation techniques has reduced the need for intermaxillary fixation following elective facial fracture repair, with only unstable comminuted fractures requiring this form of fixation. Submental intubation during fracture repair is now being used as an alternative to tracheostomy in some centres.[32]

INJURIES TO THE LARYNX AND TRACHEA

Direct trauma to the airway is rare, accounting for less than 1% of traumatic injury seen in most major centres.[33,34] The bony protection afforded to the airway by the sternum and mandible and death from asphyxia at the accident scene account for the rarity of the injury. Laryngotracheal injury can be classified as blunt or penetrating. Failure to recognise these injuries, their complications and specific pitfalls in airway management can lead to death.[35]

MECHANISM OF INJURY

BLUNT INJURY

Common causes include motor vehicle accidents where the extended neck impacts with the steering wheel or dashboard. The 'clothes-line injury' occurs when a cyclist or horse rider collides with a cable or wire causing direct injury to the upper airway. Assaults and strangulation account for the remainder of blunt injuries. Direct blows are more likely to injure the cartilages of the larynx whereas flexion/extension injuries are most commonly associated with tracheal tears and laryngotracheal transection.[36] The larynx above the cricoid cartilage is injured in 35%, manifesting as oedema, contusions, haematomas, lacerations, avulsion and fracture dislocation, most commonly of the thyroid and arytenoid cartilages.

The cricoid cartilage itself is injured in 15%, which may cause recurrent laryngeal nerve dysfunction.[37] The cervical trachea is injured in 45%.[38] Tracheal transection most often occurs at the junction between the cricoid cartilage and trachea.[39] Oedema fluid and air dissecting within submucosal layers of the larynx and trachea may cause airway obstruction. Air in the soft tissues can cause epiglottic emphysema and narrowing of the supraglottic airway.[40] Straining, talking and coughing may worsen the oedema.

Common associations with blunt laryngotracheal injury include thoracic spine injury (15.5%), closed head injury (8.5%) and vascular injuries (11.3%).[33] Up to 96% of patients with laryngotracheal trauma also have maxillofacial injuries.[34]

PENETRATING INJURY

Penetrating injuries usually result from stab or gunshot wounds. The anterior triangle of the neck is the most common site of entry. The cervical trachea is most commonly involved in stab wounds. The larynx is injured in about one-third of those with upper-airway injuries.[38] Of patients with penetrating laryngotracheal trauma, 19% also had cervicothoracic vascular injury, 15% had oesophageal injury and 34% had chest trauma.[33]

ASSESSMENT OF INJURY

Definitive investigation and management depend on the airway status and presence of associated injury. The degree of injury is not readily assessable on the basis of any one clinical symptom or sign (**Box 76.1**) and delayed diagnosis is common. The emphasis has moved towards CT scanning in the first instance in stable patients with laryngeal tenderness, endolaryngeal oedema and small haematomas. CT demonstrates fractures of cartilages, haematomas and other injuries. Further investigation with fibreoptic laryngotracheoscopy under local anaesthesia can be used to demonstrate vocal cord dysfunction, integrity of the cartilaginous framework and laryngeal mucosa. Rigid laryngoscopy can be used when adequate visualisation is not achieved with the former. Pharyngo-oesophagoscopy, contrast studies, open exploration and angiography may be required to exclude aerodigestive tract and major vascular injuries.

AIRWAY MANAGEMENT

Up to three-quarters of patients with laryngotracheal injury require intubation.[34] The safest mode of intubation is via tracheostomy under local anaesthesia

Box 76.1 Clinical features in laryngotracheal injury

- Symptoms
  - Respiratory distress, stridor, noisy breathing
  - Neck tenderness or oedema
  - Hoarseness
  - Dysphonia
  - Cough
  - Dysphagia
- Signs
  - Abnormal laryngeal contour
  - Subcutaneous emphysema
  - Cervical ecchymosis
  - Haemoptysis
- Investigations
  - Plain radiography
    - Air in soft tissues
    - Pneumomediastinum
    - Pneumothorax
    - Cervical spine fracture
  - CT scan
    - Cartilage and soft-tissue injury
    - Altered airway patency
  - Laryngoscopy
    - Vocal paralysis
    - Mucosal or cartilage disruption
    - Haematoma
    - Laceration

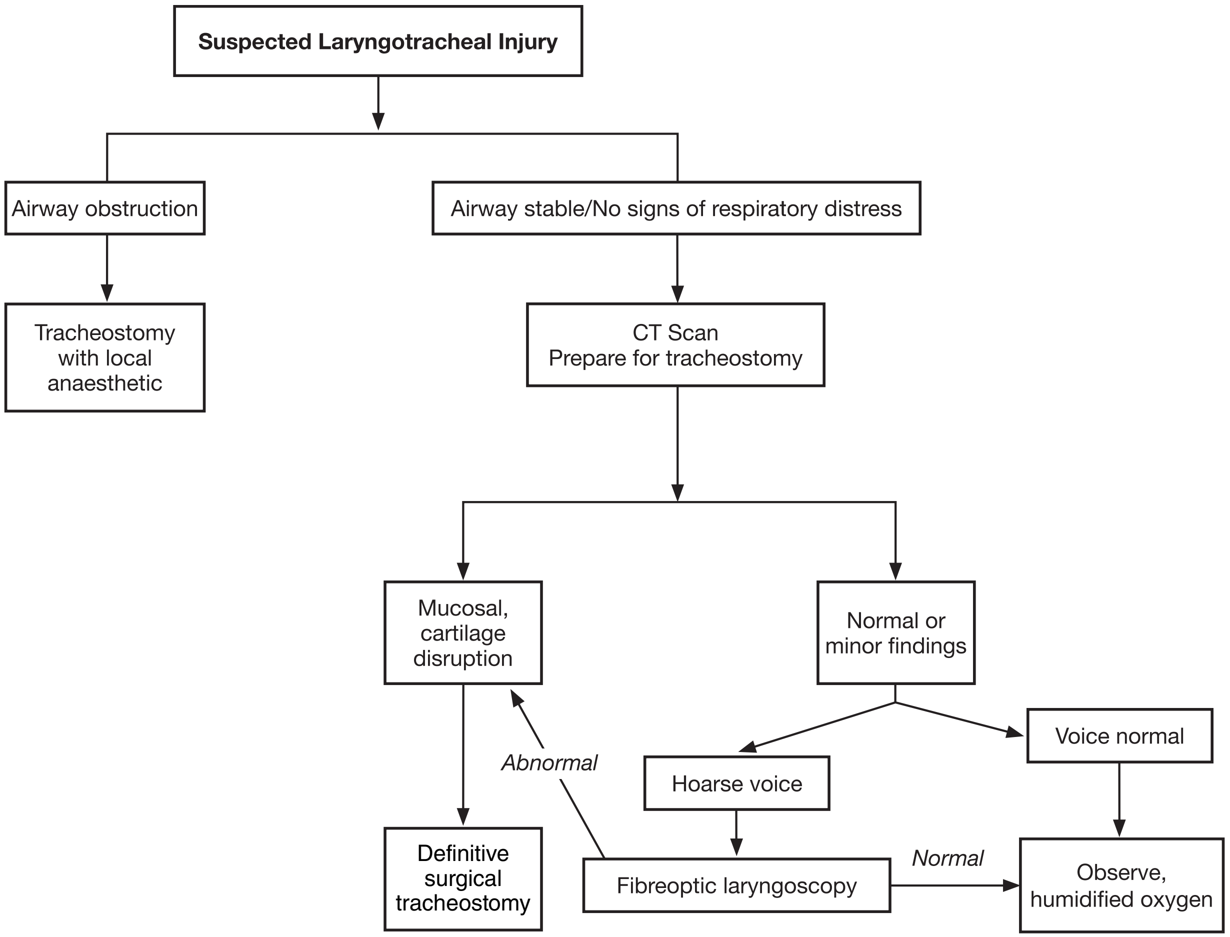

Figure 76.3 Airway assessment and management algorithm for suspected laryngotracheal trauma. CT=computed tomography.

(**Fig. 76.3**). Blind intubation can lead to complete airway obstruction owing to creation of false passages and mucosal disruption.[35] Cricoid pressure can lead to laryngotracheal separation and is contraindicated. Positive-pressure ventilation can rapidly worsen air leaks and wherever possible the patient should maintain spontaneous respiration until a tube has been placed distal to the site of injury. Cricothyroidotomy is not recommended as it may compound laryngeal injury. In an emergency, gaping airway wounds (e.g. with tracheal transection) can be intubated under direct vision pending subsequent surgery.

Chest injuries

Ubbo F Wiersema

Chest injuries account for a quarter of all trauma deaths. Immediate death from severe blunt trauma is usually due to blunt rupture of the thoracic aorta, heart or major vessel. Patients who survive to hospital presentation may still have life-threatening chest injuries that require immediate intervention. The majority can be managed with simple measures such as intercostal tube thoracostomy, oxygen therapy, analgesia and mechanical ventilation.[1–3] Tension pneumothorax, open pneumothorax or massive haemothorax require immediate intercostal tube drainage. Urgent thoracotomy is indicated for pericardial tamponade, diaphragmatic rupture and massive haemothorax with ongoing bleeding.[2] Following the resuscitation phase, extensive pulmonary contusions with respiratory failure may require prolonged ventilatory support. Chest injuries that are initially missed may also significantly prolong intensive care stay.

IMMEDIATE MANAGEMENT

Identification of chest injuries forms a core component of the initial assessment of a patient with major trauma – both because immediate intervention can be life saving, and because restoration of respiratory and circulatory stability minimises secondary injury to extrathoracic organs, particularly traumatic brain injury.[1] A history of the mechanism and force of injury should be sought as this will guide the likelihood of different injuries and determine the need for more extensive investigation.

During the primary survey the airway patency is ensured, oxygen administered by face mask and ventilation assessed. The degree of circulatory compromise is determined and obvious external bleeding is controlled. Two large-bore intravenous cannulae are sited, blood samples taken and intravenous fluids commenced. Intravenous opioid analgesia is given as repeated small boluses, titrated to effect. Complete exposure is important to facilitate examination of the chest and facilitate intercostal tube insertion, if required. With penetrating trauma all surface wounds must be located so that the pathway of potential injuries can be determined.[2] There are four life-threatening chest injuries that require immediate intervention:

- tension pneumothorax
- open (sucking) pneumothorax
- massive haemothorax
- pericardial tamponade.

In addition, the clinical features of flail chest should be sought, as these will no longer be apparent if positive-pressure ventilation is instituted (see below). Interventions required during initial management are outlined in **Box 77.1**. A chest radiograph is integral to the initial assessment and should be performed promptly. However, the severity of physiological derangement will dictate the time available for confirmatory imaging, and a patient with clinical signs of tension pneumothorax should undergo immediate intercostal tube thoracostomy before the chest radiograph (see below). If there is no physiological improvement after unilateral tube thoracostomy, a second drain should be inserted in the contralateral chest.

Lung ultrasound can be completed faster than a chest radiograph, and has significantly higher diagnostic accuracy for pneumothorax and haemothorax when performed by experienced operators.[4] However, clinicians not experienced with lung ultrasound should avoid decision-making based on this technique. Subcostal ultrasonography of the heart to look for pericardial fluid forms part of the focused assessment with sonography for trauma (FAST) and should be performed with penetrating chest trauma, or if there is haemodynamic instability with blunt trauma.[2,4,5] An electrocardiogram (ECG) is important in the assessment for blunt cardiac injury.[2,6]

Endotracheal intubation and mechanical ventilation are indicated for the patient with a compromised airway, severe head injury, or gross hypoventilation and/or hypoxaemia not attributable to pneumothorax. Haemodynamic instability should be anticipated (**Box 77.2**). Rarely, emergency cricothyroidotomy or tracheostomy is required when an airway obstruction cannot be bypassed by translaryngeal intubation. A nasogastric or orogastric tube (if facial injuries are suspected) should be inserted to decompress the stomach after endotracheal intubation.

PNEUMOTHORAX

Pneumothorax visible on the initial chest radiograph should be treated with insertion of an intercostal tube connected to an underwater seal drainage system

Box 77.1 Immediate management of chest trauma

Indications for intercostal drain insertion
- Pneumothorax
- Haemothorax

Indications for urgent thoracotomy
- Pericardial tamponade
- Diaphragmatic rupture
- Massive haemothorax with ongoing bleeding

Indications for emergency thoracotomy
- Witnessed loss of vital signs after penetrating trauma

Indications for intubation and positive pressure ventilation
- Airway compromise
- Gross hypoventilation and/or hypoxaemia (not attributable to pneumothorax)
- Severe head injury

Box 77.2 Causes of cardiovascular collapse on induction of anaesthesia and positive-pressure ventilation in chest-injured patients

- Excessive anaesthetic agent
- Hypovolaemia
- Oesophageal intubation with hypoxaemia
- Tension pneumothorax
- Pericardial tamponade
- Anaphylaxis
- Systemic air embolism
- Severe blunt cardiac injury

(**Fig. 77.1**). A single bottle drainage system without suction is usually adequate. Low-pressure suction (20 cmH_2O) is applied if the pneumothorax fails to fully resolve, or if there is associated haemothorax (**Fig. 77.2**). A three-bottle system (or a commercially available three-in-one system) allows more accurate control of suction (**Fig. 77.3**). Use of antibiotics (to prevent empyema) is controversial, but contamination during intercostal tube insertion is common and a 24-hour course of a first-generation cephalosporin may be appropriate.[7,8]

Tension pneumothorax results from progressive accumulation of air in the pleural space, positive intrapleural pressure and cardiorespiratory decompensation.[9] In awake patients, slow development of positive intrapleural pressure leads to progressive hypoxaemia and respiratory distress. Tachycardia is common, but preserved venous return maintains cardiac function and blood pressure. In sedated patients on positive-pressure ventilation, the positive intrapleural pressure throughout the respiratory cycle can lead to the rapid development of hypoxaemia. Cardiac output is compromised by obstructed venous return; hypotension is prominent and may progress to cardiac arrest. In both awake and ventilated patients, chest signs (hyperexpansion, decreased breath sounds and tracheal deviation) are not reliably present.[9]

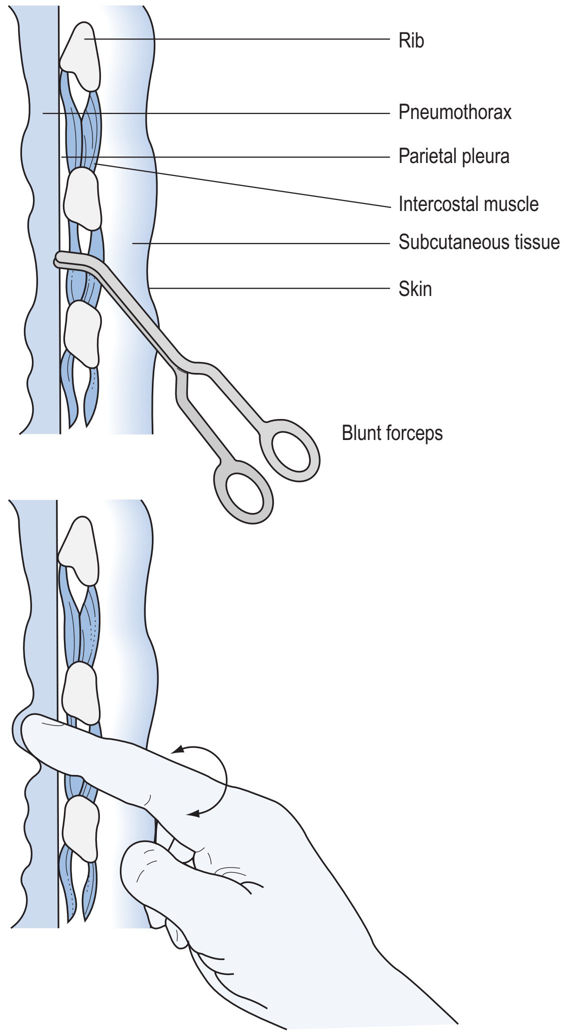

Figure 77.1 Intercostal tube insertion. After sterile preparation and drape 1% lidocaine is infiltrated in the midaxillary line at the level of the nipple. A 2–3 cm transverse skin incision is made. Dissection is performed by blunt forceps down to the pleura passing just superior to the rib surface to avoid injury to neurovascular structures. A gloved finger is used to confirm separation of lung from chest wall. A large-bore (28–32 Fr) intercostal tube is inserted without a trocar and advanced in a postero-superior direction. Curved forceps clamped to the distal side hole of the tube can be used to guide the tube through the chest wall. The tube is immediately connected to an underwater seal drainage system (see Figs 77.2 and 77.3) and checked for satisfactory drainage and tidal rise and fall in fluid level with respiration. Non-absorbable sutures are used to seal the skin incision around the tube and secure the tube. The intrathoracic position of the tube is checked with a chest radiograph.

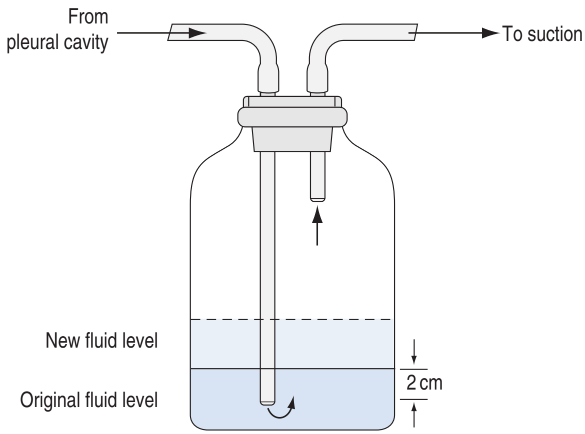

Figure 77.2 Single-bottle drainage system for haemopneumothorax. Air drainage will become more difficult if there is also fluid drainage, raising the fluid level in the bottle (dashed line) and increasing the depth of immersion of the hollow rod. This can be overcome by applying low-pressure suction (20 cmH_2O). Arrows indicate direction of air flow.

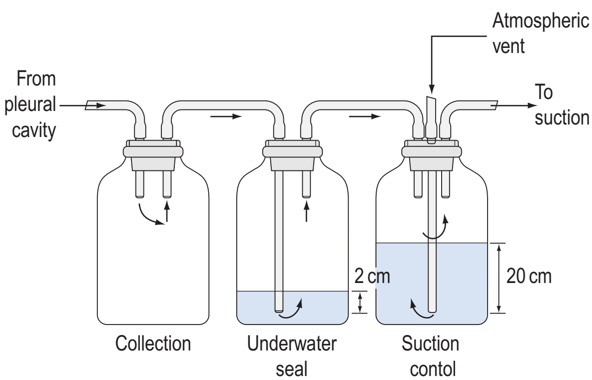

Figure 77.3 Three-bottle chest drainage system. The first bottle (connected to the intercostal tube) is a fluid collection chamber, the second functions as a one-way valve (underwater seal), and the third (connected to wall suction) limits the amount of suction applied. The level of suction is set by adjusting the depth of the atmospheric vent whilst ensuring that it bubbles continuously. Commercially available drainage systems function on the same principles as the three-bottle system. Arrows indicate direction of air flow.

If tension pneumothorax is suspected clinically, an intercostal tube should be inserted immediately, prior to the chest radiograph. Blunt dissection and insertion of a gloved finger into the pleural space allow rapid decompression of tension, prior to intercostal tube insertion.[7] Needle thoracostomy with a large-bore cannula inserted into the second intercostal space in the midclavicular line may be used to drain air more rapidly for patients in extremis. However, this is rarely necessary and may puncture the lung, or a blood vessel, fail to reach the pleural space, or kink when the needle is removed from within the cannula.[7] Furthermore the landmarks for needle thoracostomy are often identified incorrectly, increasing the risk of adverse outcome. Whether successful or not, needle thoracostomy must be followed by intercostal tube drainage.

Open pneumothorax occurs when a chest wall defect allows direct communication of a pneumothorax with the exterior, usually after penetrating trauma. Tension can develop if air can enter but not exit through the defect. Treatment involves application of an occlusive, non-adherent, square dressing sealed along three edges over the wound after sterile skin preparation. This allows air to escape but not enter through the wound, but should be followed by intercostal tube insertion at a site not immediately adjacent to the wound.

Simple pneumothorax may develop tension at any stage, especially with positive-pressure ventilation (see Box 77.2). A small pneumothorax may be missed on the initial chest radiograph. In the supine position pleural air collects antero-inferiorly and is demonstrated radiologically by a deep sulcus sign or increased radiolucency of one side of the chest compared with the other (**Fig. 77.4**).[10]

Occult pneumothorax is defined as visible on chest CT (or upper slices of an abdominal CT) but not plain radiograph. Drainage is not usually required, but should be considered if prolonged surgery is anticipated, there is significant cardiorespiratory compromise, or interhospital transport is necessary. With a conservative approach the patient should be carefully monitored for deterioration from expansion of the pneumothorax.[11,12]

Subcutaneous emphysema over the chest wall in a patient with blunt chest trauma is almost always associated with pneumothorax, but should raise suspicion of other injuries (**Box 77.3**). The pneumothorax may not be visible on chest radiograph, either because it is obscured by the emphysema, or because it has largely decompressed into subcutaneous tissues. An intercostal tube should be inserted.

If there is no associated fluid collection, the intercostal tube can be removed once the pneumothorax is no longer visible on chest radiograph and there has been no air drained for at least 24 hours. Persistent air leak and incomplete drainage of a pneumothorax after intercostal tube insertion should prompt investigation for tracheobronchial injury. However, the depth of the tube within the pleural space and tubing connections should be checked to ensure that air is not being inadvertently entrained from outside the chest. Incomplete drainage with no air leak is usually due to tube malplacement.

HAEMOTHORAX

Haemothorax visible on chest radiograph should be drained as completely as possible (Fig. 77.1). The tube can be removed once radiographic clearance is achieved,

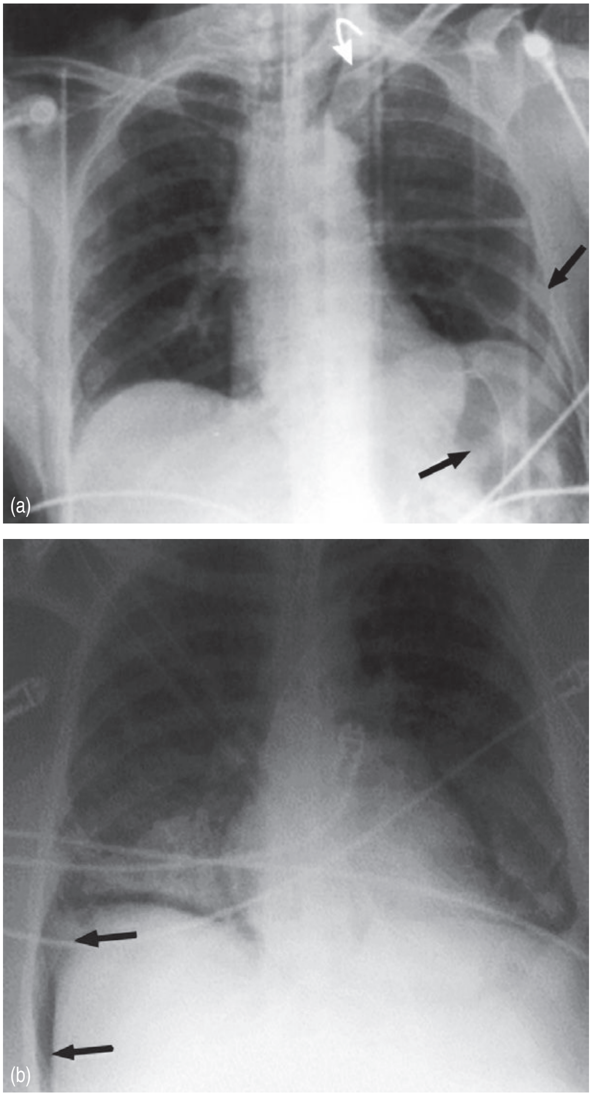

Figure 77.4 (a) Moderate-sized left pneumothorax on supine chest radiograph. The visceral pleura is visible at the lung apex (curved arrows). Hyperlucency is visible in the left lower chest (straight arrows), (b) Supine chest radiograph of right-sided deep sulcus sign (arrows). *(From Miller LA. Chest wall, lung, and pleural space trauma. Radiol Clin North Am 2006; 44(2):213–24, viii.)*

Box 77.3 Causes of pneumothorax, subcutaneous emphysema and/or pneumomediastinum

Oesophageal injury
Facial or pharyngeal injury
Abdominal or retroperitoneal injury (air tracking up)

with <100 mL per 24 hours drainage. A small haemothorax (<300 mL) (visible on ultrasound or CT) may initially be managed conservatively, but should be drained if it enlarges. Persistent opacity on chest radiograph after tube placement should be investigated with CT or ultrasound to determine whether there is significant undrained fluid (see retained haemothorax below).

Massive haemothorax, defined as >1500 mL, causes life-threatening circulatory compromise from hypovolaemia and vena caval compression, as well as hypoxaemia. This requires immediate tube drainage and consideration of surgical exploration.[12] If the amount of ongoing bleeding following initial drainage is low, the patient remains haemodynamically stable after initial resuscitation and the blood is venous in appearance, the patient can be managed with close observation. Ongoing bleeding of >200 mL per hour, or >600 mL over 6 hours (massive haemothorax equivalent), is an indication for thoracotomy.

PERICARDIAL TAMPONADE

Pericardial tamponade should be suspected in any patient with a gunshot wound to the chest, or stab wound to the precordium. It occurs rarely with blunt trauma, but should be suspected if there is hypotension out of proportion to blood loss, and distended neck veins. Pulsus paradoxus may be detected in the spontaneously breathing patient. The differential diagnosis includes tension pneumothorax (most likely), cardiogenic shock from severe blunt cardiac injury, or inadequate resuscitation. Pericardial fluid can be detected with ultrasound via a subcostal view (as part of the FAST scan).[4] Echocardiography, or operative subxiphoid window, can be used if diagnostic uncertainty remains.

Haemodynamically unstable patients should undergo thoracotomy.[13] Subxiphoid pericardiotomy can be performed in selected stable patients, but may require conversion to open thoracotomy. Needle pericardiocentesis is rarely effective in the acute setting, but may have a role in the drainage of delayed pericardial effusions following stab wounds.[13]

CARDIAC ARREST AND EMERGENCY THORACOTOMY

External cardiac massage is invariably unsuccessful in the trauma setting, and may cause further injury to intrathoracic structures, and obstruct access to the patient for more potentially useful interventions such as bilateral pleural decompression. For patients with witnessed loss of vital signs after penetrating chest trauma, emergency thoracotomy should be considered if suitably experienced medical personnel are available.[13] This is rarely successful for blunt trauma. The standard approach is a left-sided antero-lateral

thoracotomy. Access to the thoracic cavity facilitates specific interventions:[8]

- release of pericardial tamponade
- control of intrathoracic bleeding
- control of massive air embolism, or bronchopleural fistula
- cross-clamping of the descending aorta
- internal cardiac massage.

These temporising (damage control) measures are followed by transfer to the operating room for completion of surgery:[14]

- definitive repair of cardiac injury
- pulmonary tractotomy, wedge resection, or lobectomy/pneumonectomy for lung injury
- Repair or grafting of vascular injury.

Postoperatively the patient is admitted to ICU for rewarming, correction of coagulopathy and resuscitation.

SPECIFIC INJURIES

After addressing initial management issues, a secondary survey and further imaging are performed to identify all injuries. Extrathoracic injuries causing haemodynamic instability should be addressed (e.g. laparotomy) before completion of thoracic imaging; unstable patients should not be transferred to an imaging department away from resuscitation facilities. With the widespread availability of multislice helical CT, chest CT angiography has become the primary imaging modality for the diagnosis of specific chest injuries. This is usually performed as part of a whole body 'pan scan' (CT head, neck, chest, abdomen and pelvis) with injection of intravenous contrast timed to provide aortic angiography. Endotracheal intubation and mechanical ventilation may be required to facilitate CT (e.g. the combative trauma patient with ethanol intoxication). Exposure to high doses of radiation has raised concern about the liberal use of the pan scan.[15] Chest CT is unlikely to identify additional significant injuries if the chest radiograph is normal and the mechanism of injury was low risk.[16]

BLUNT AORTIC INJURY

Blunt aortic injury usually occurs as a result of severe deceleration injury causing a tear at the junction between the fixed descending aorta and the mobile aortic arch, just distal to the origin of the left subclavian artery.[5] Less frequently the ascending aorta (or arch vessels) is injured by direct trauma. Most patients with blunt aortic injury die at the scene from complete aortic wall transection, or associated injuries. Of those that reach hospital, 90% will have a significant aortic injury and up to 50% of these will die before repair.[5] Blunt aortic injuries may be divided into:[17–19]

- *significant aortic injury*, with disruption of the intima and full thickness of the media; there is a high risk of rupture
- *minimal aortic injury*, with laceration limited to the intima and inner media – radiologically this manifests as an intimal flap or pseudoaneurysm <1 cm in length, with minimal or no periaortic haematoma; there is a low risk of rupture.

Aortic injury should be suspected if the mechanism of injury is suggestive of rapid deceleration, such as high-speed (greater than 50 km/h) motor vehicle or motorcycle crash, pedestrian hit by a vehicle, or fall from a height greater than 3 metres.[5,20] Clinical signs of significant aortic injury include unequal upper limb pulses, pseudocoarctation or interscapular murmur, but these are often absent.

Historically chest radiography has been the screening test (to detect mediastinal haematoma), and aortic angiography the diagnostic test for blunt aortic injury.[18] Helical CT chest angiography is now the diagnostic test of choice, although transoesophageal echocardiography may be more appropriate in certain circumstances:[19–21]

- *Chest radiograph* features of blunt aortic injury are caused by distortion of normal mediastinal contour by periaortic haemorrhage. A widened mediastinum (greater than 8 cm at the level of the aortic knuckle) is the principal finding (**Box 77.4**).[22] A supine chest radiograph accentuates mediastinal width and in the acute trauma setting is often of suboptimal quality. Measurement of left mediastinal width (>6 cm), or left mediastinal width to mediastinal width ratio (>0.6), may improve specificity.[22]
- *Multislice helical (multiple row detector) chest CT angiography* (with more than 16 detectors) provides sufficient resolution in multiple planes for CT to be used as the sole diagnostic test, and has largely superseded other imaging modalities for diagnosis of aortic injury.[19]
- *Single-slice helical chest CT* may demonstrate direct signs of aortic injury. However, more commonly aortic injury manifests indirectly with periaortic haematoma, and a further diagnostic test is required.[19] Nevertheless by differentiating periaortic

Box 77.4 Chest radiograph signs of blunt aortic injury

Signs of periaortic haematoma	Indirect signs
Widened mediastinum (>8 cm)	Left haemothorax
Obscured aortic knuckle	Left pleural cap
Opacification of aortopulmonary window	Fractured first or second ribs
Deviation of trachea, left main bronchus or nasogastric tube	
Thickened paratracheal stripe	

haematoma from other types of mediastinal haematoma, and excluding other causes of an abnormal mediastinal contour, single-slice helical CT provides a useful screening test[19] where multislice CT is not available.

- *Transoesophageal echocardiography* is rapid and portable, making it suitable for examination of the unstable patient (e.g. in the operating room). It provides high diagnostic accuracy for aortic injury and also allows examination for blunt cardiac injury.[21] However, imaging of the distal ascending aorta, proximal arch and major branches is limited. Thus if signs of mediastinal haematoma are detected, but an aortic injury is not identified, further diagnostic imaging is warranted.[19] It is contraindicated if an upper airway or oesophageal injury is suspected.
- *Aortic angiography* is relatively time consuming and requires transfer of the patient to the angiography room, making it potentially hazardous for the unstable patient. However, it is the preferred diagnostic test if branch vessel injury is suspected (**Box 77.5**), or if uncertainty remains after other diagnostic imaging.[19] It is also necessary for endovascular aortic repair, and may be required for operative planning.

Significant aortic injury requires prompt surgical or thoracic endovascular aortic repair (TEVAR).[5,18,23] However, this should not take priority over other life-saving interventions (e.g. control of external or pelvic bleeding, laparotomy, or craniotomy for intracranial haemorrhage). Open surgical repair requires a left postero-lateral thoracotomy and selective right-lung ventilation. Operative techniques include direct repair (clamp and sew), or techniques that maintain distal aortic perfusion (bypass). [5,18,23] The latter reduce the risk of postoperative paraplegia from spinal cord ischaemia, but often require systemic heparinisation, which may exacerbate bleeding from other injuries. Sometimes a lumbar drain for cerebrospinal fluid (CSF) drainage is placed perioperatively to improve spinal cord perfusion and potentially reduce the incidence of paraplegia. Postoperatively CSF is drained freely to maintain a CSF pressure less than 10 mmHg. The drain is removed after 3 days if there are no neurological complications. Surgery should be deferred, sometimes indefinitely, if severe associated injuries or co-morbidities make the operative risk unacceptably high. In such cases TEVAR may still be feasible and in many institutions has become the primary method of aortic repair.[5,18,23] The procedure involves isolation of the injured section of aorta by deployment of endoluminal stents, usually via cannulation of the iliac or femoral artery. Although less invasive and less time consuming than open repair, long-term outcome data are lacking and complications may occur.[5,18,23] Endoleaks can arise from incomplete exclusion of the site of injury, or inadequate apposition along the lesser curve of the aorta. Lesions immediately adjacent to the left subclavian artery may require stent coverage of the artery to fully exclude the site of injury. This may result in endoleak due to retrograde blood flow from the left subclavian artery, or ischaemia of the left upper limb or vertebral artery territory requiring left subclavian to left carotid artery grafting. Device collapse causing catastrophic aortic occlusion can occur if the endograft is oversized. Serial follow-up imaging is recommended after TEVAR[5,18]

In patients unfit for immediate intervention, beta blocker +/− vasodilator therapy is given as tolerated to decrease aortic wall shear forces, aiming for a systolic blood pressure <100–120 mmHg and heart rate <100 beats per minute. Minimal aortic injury, with no associated periaortic haematoma or pseudoaneurysm on initial CT can be managed expectantly, with serial imaging.[17] Development of pseudoaneurysm, or periaortic haematoma should prompt consideration for TEVAR.[18]

BLUNT CARDIAC INJURY

Blunt cardiac injury results from compression of the heart between the sternum and the spine, abrupt pressure changes within cardiac chambers, or deceleration shear injury. A wide spectrum of injuries has been described, but may be classified according to the clinical sequelae and need for intervention:[6]

- *Minor ECG and cardiac enzyme abnormalities:* sinus tachycardia and premature beats are common, but usually resolve within 24 hours without intervention.
- *Complex arrhythmias:* these may cause heart failure, or persistent hypotension, and may warrant antiarrhythmic therapy.
- *Free wall rupture:* this is usually fatal, but atrial rupture may present with haemopericardium +/− tamponade. Immediate drainage and repair is required.
- *Heart failure:* this may develop from gross myocardial injury, septal rupture (causing left to right shunt), or valvular injury (causing regurgitation). The latter may not manifest until weeks later. Septal rupture and severe valvular injury require surgery. Myocardial dysfunction may require inotropic support.
- *Coronary artery injury:* this is very rare and ST elevation on ECG is more likely to be due to a primary myocardial infarction.

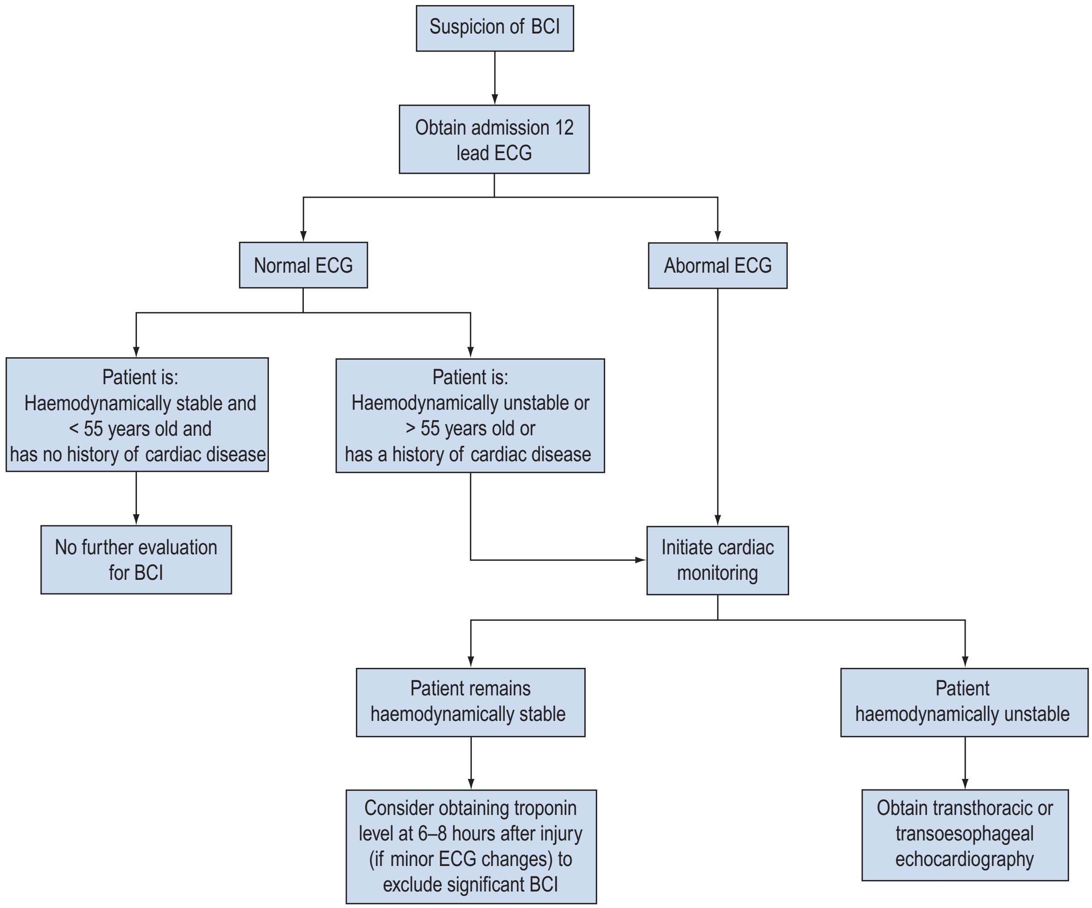

Figure 77.5 Algorithm for evaluation of patients suspected of having blunt cardiac injury (BCI). *(Modified from Schultz JM, Trunkey DD. Blunt cardiac injury. Crit Care Clin 2004;20:57–70.)*

All patients should have an ECG on admission (**Fig. 77.5**). If this is normal and the patient is young, haemodynamically stable and has no history of cardiac disease, the risk of significant injury is very low and no further cardiac evaluation is required. Other patients should be monitored for late sequelae of significant cardiac injury (arrhythmia or heart failure).[6] Patients who remain haemodynamically stable with only minor ECG changes, and who have a normal troponin level at 6–8 hours post injury, have a low risk of cardiac complications.[24]

Echocardiography is indicated for patients with hypotension unexplained by other injuries, heart failure, or persistent arrhythmias.[2] Undisplaced sternal fracture does not of itself warrant cardiac evaluation.[25]

TRACHEOBRONCHIAL INJURY

Blunt rupture of the trachea or bronchi results from crush injury or rapid deceleration with shearing of the airway between a fixed trachea and mobile lungs. The proximal right main bronchus is the most common site of injury.[2,26] Large injuries present with respiratory distress, subcutaneous emphysema and haemoptysis (Box 77.3).[27] The chest radiograph demonstrates pneumothorax and mediastinal emphysema. Dramatic deterioration may follow the institution of positive-pressure ventilation (Box 77.2). With smaller injuries, initial findings are often overshadowed by associated injuries with delay in diagnosis. Persistent pneumothorax with a large air leak, or recurrent pneumothoraces and pulmonary collapse, should prompt further investigation. Flexible bronchoscopy confirms the diagnosis and identifies the level of injury. Treatment is usually primary repair, although non-operative management has been described.[28] Late complications of either approach include post obstructive pneumonia, empyema or bronchiectasis.[26]

With penetrating trauma the cervical trachea is most commonly injured. Immediate management involves tracheal intubation (preferably with flexible bronchoscopy) with the cuff positioned distal to the tear to ablate

the air leak. With a large neck wound the endotracheal tube can be passed directly through the wound in emergency situations.

DIAPHRAGMATIC RUPTURE AND DIAPHRAGMATIC PARESIS

The usual mechanism of diaphragmatic rupture is gross abdominal compression from direct vehicular intrusion. The risk of rupture is higher with lateral impact collisions, but not seat belt use.[29] Associated injuries are very common.[29] Rupture of the left hemidiaphragm is more common because the right hemidiaphragm is congenitally stronger and protected by the liver.

Symptoms (dyspnoea and chest pain) are nonspecific. Rarely bowel sounds are audible on chest auscultation. Diagnostic chest radiograph findings are herniation of bowel into the thoracic cavity and nasogastric tube above the left hemidiaphragm. Indirect signs include an elevated or distorted diaphragmatic outline, or pleural effusion, but these may be obscured by adjacent pulmonary pathology, phrenic nerve injury, or by positive-pressure ventilation.[30] The low diagnostic accuracy of chest radiography often results in delayed diagnosis unless further imaging is performed. Multislice helical CT has high diagnostic accuracy, but magnetic resonance imaging, or video-assisted thorascopy (VATS) may be required if uncertainty persists.[30,31] Prompt operative repair is important to prevent bowel incarceration or perforation. The choice of surgical approach (laparotomy or thoracotomy) is dictated by associated injuries.

Traumatic phrenic nerve palsy, or postoperative diaphragmatic dysfunction, may go unrecognised whilst the patient is on mandatory positive-pressure ventilation. With the transition to spontaneous ventilation, paradoxical abdominal and chest wall movement, reduced vital capacity and difficulty weaning from ventilatory support become evident.

OESOPHAGEAL INJURY

Rupture of the oesophagus from blunt trauma is rare. Penetrating trauma usually causes injury to the cervical portion of the oesophagus. Oesophageal injury may also result from attempted endotracheal intubation or gastric tube insertion during resuscitation of the trauma patient.[32] Clinical features include chest pain, dysphagia, pain on swallowing and subcutaneous emphysema (Box 77.3). Chest radiograph findings include pneumothorax and/or hydrothorax, mediastinal emphysema, or widened mediastinum.[27] Prompt diagnosis by oesophagoscopy or gastrograffin swallow is important. Treatment is immediate surgical repair.[32] Delayed recognition or repair (more than 12 hours post injury) leads to septic shock from mediastinal contamination. Extensive irrigation and drainage is then required, but postoperative complications are common.[32]

PULMONARY INJURY

Pulmonary contusion is characterised by interstitial haemorrhage and oedema, with a secondary inflammatory reaction. Clinically there are signs of increased work of breathing, associated with impaired gas exchange and sometimes haemoptysis. The chest radiograph demonstrates patchy interstitial infiltrates, or consolidation not confined to anatomical segments. Gas exchange and radiographic findings may initially be unremarkable, with deterioration over the first 24–48 hours.[3,10] CT and lung ultrasound are more sensitive at detecting contusion, and quantification of lung volume affected predicts risk of ARDS.[33,34] In the absence of complications (ARDS, pneumonia, or aspiration) clinical and radiological recovery can be expected within 3–5 days.[10]

Treatment is supportive with humidified oxygen therapy, and encouragement of deep breathing and coughing in the spontaneously breathing patient. Noninvasive ventilation can be used in selected patients if gas exchange is poor. Intubation and mechanical ventilation is indicated for refractory hypoxaemia, or if intubation is required for non-pulmonary reasons. Routine corticosteroids are not indicated. Antibiotics should be reserved for superimposed pneumonia.[3]

Pulmonary laceration occurs when disruption of lung architecture, with formation of an air or blood-filled cavity, occurs after blunt or penetrating trauma. On chest radiography, lacerations are often initially obscured by adjacent contusion, but typically take many weeks to resolve and may be complicated by abscess formation or bronchopleural fistula.[10]

BONY INJURIES

Half of all rib fractures are missed on plain chest radiography, but should be suspected if there is localised tenderness over the chest wall. Good analgesia to prevent pulmonary complications from sputum retention is essential.[35] This risk may not be clinically apparent initially, but deterioration in respiratory status over the next few days should be anticipated, especially in the elderly, smokers, or patients with pre-existing pulmonary disease. First- and second-rib fractures, scapula fracture and sternoclavicular dislocation are markers of high-energy trauma.[3]

Most sternal fractures occur in restrained occupants involved in frontal impact vehicular crashes. Associated thoracolumbar spine fractures are common.[25] Blunt cardiac injury should be suspected with displaced sternal fractures.[25]

FLAIL CHEST

Fracture of at least four consecutive ribs in two or more places results in a flail segment with paradoxical movement of the chest wall during tidal breathing (**Fig. 77.6**).[3] Associated pulmonary contusion is often present. Younger patients with no other major injuries, no

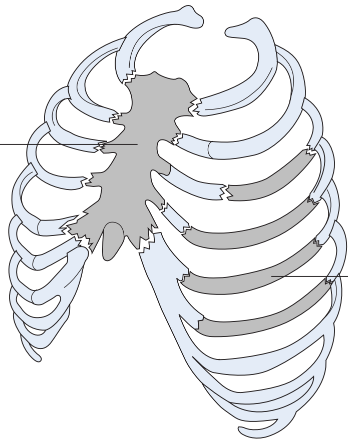

Figure 77.6 Types of flail chest. *(Modified from Wanek S, Mayberry JC. Blunt thoracic trauma: flail chest, pulmonary contusion, and blast injury. Crit Care Clin 2004;20:71–81.)*

pulmonary comorbidities and good analgesia can often be managed with non-invasive ventilation or oxygen therapy alone.[36] Deteriorating gas exchange and sputum retention are indications for intubation and mechanical ventilation. Prolonged ventilatory support is often not necessary in patients whose associated injuries and co-morbidities are not severe. Surgical stabilisation has been advocated for severe flail to reduce duration of ventilation.[37]

EXTRAPLEURAL HAEMATOMA

Traumatic extrapleural haemorrhage arises when chest wall bleeding does not enter the pleural space.[38] Chest radiography shows a parietal shadow that does not cause blunting of the costophrenic angle or shift with gravity. A large haematoma should be evacuated with an intercostal tube or by thoracotomy.

SYSTEMIC AIR EMBOLISM

This is more frequent with penetrating injuries and is immediately life threatening. The typical presentation is circulatory collapse after institution of positive-pressure ventilation, when the pulmonary air-space pressure exceeds pulmonary venous pressure (Box 77.2). Focal neurological changes in the absence of head injury also suggest the diagnosis. Characteristic head CT findings have been described.[39]

When suspected, maintenance of spontaneous ventilation is preferred. If positive-pressure ventilation is necessary, an Fi_{O_2} of 1.0 should be used, with ventilatory pressures and volumes reduced to a minimum. Selective lung ventilation, using a double-lumen endotracheal tube or bronchial blocker, and/or high-frequency ventilation, should be considered.[39] However, urgent thoracotomy, with hilar clampling or lung isolation, is usually indicated.[13] Hyperbaric oxygen therapy has been used to treat cerebral air embolism, but is often impractical.[39]

COMPLICATIONS AND ICU MANAGEMENT

On admission to ICU, rewarming, correction of coagulopathy and ongoing fluid resuscitation are often required. Pericardial tamponade and persistent air leak should be anticipated in post-thoracotomy patients.[14] A restrictive approach to fluid therapy is indicated for patients who have undergone lung surgery. However, care should be taken to ensure adequate fluid resuscitation. A judicious transfusion policy should be employed with all patients.[40]

As with other critically ill or injured patients, prophylactic measures against thromboembolism[41] and upper gastrointestinal stress ulceration should be used. Adequate nutrition is important to ameliorate the hypermetabolic and catabolic metabolic changes, reduce the incidence of sepsis and improve outcome. Nutrition should be instituted early, preferably via the enteral route.

ACUTE RESPIRATORY FAILURE AND MECHANICAL VENTILATION

Respiratory complications are common. When acute lung injury occurs early after trauma, common causes are pulmonary contusion, aspiration, massive transfusion and prolonged shock or delayed resuscitation with severe systemic inflammatory response. Aspiration with persistent lobar collapse is an indication for bronchoscopy to exclude bronchial obstruction from particulate obstruction. When lung injury develops several days later, sepsis of either pulmonary or non-pulmonary origin is a more likely cause.

The approach to mechanical ventilation for intubated patients follows the same principles as with other critically ill patients.

- Patients with acute lung injury/ARDS should be ventilated with a lung-protective strategy. However, high PEEP and permissive hypercapnia are contraindicated if there is associated head injury.
- Patients with pneumothorax or tracheobronchial injury should be managed with low PEEP, low peak airway pressures, and early transition to spontaneous ventilation if possible.
- Patients with flail chest may benefit from the splinting effect of moderate levels of PEEP.
- Failure to wean from mechanical ventilation should raise suspicion of fluid overload, diaphragmatic injury, cardiac dysfunction or flail.

Select patients with hypoxaemia refractory to optimal mechanical ventilation may be supported with veno-venous extracorporeal membrane oxygenation.

SPUTUM RETENTION

Sputum retention leads to progressive pulmonary collapse, with impaired gas exchange, increased work of breathing and increased risk of infection. Smokers, or patients with pre-existing respiratory disease, are particularly at risk. In the spontaneously breathing patient, good analgesia and incentive spirometry facilitate coughing and deep breathing. In the intubated/ventilated patient, humidification, tracheal suctioning and regular position changes are important.

ANALGESIA

Adequate analgesia is essential for deep breathing and effective coughing, which, if achieved, will reduce the likelihood that endotracheal intubation will be needed for less severely injured patients. Analgesia also facilitates chest physiotherapy and early mobilisation, reducing pulmonary morbidity. The choice of analgesia depends on the severity of illness and may vary over time. Options include the following:[35]

- *Intravenous morphine or fentanyl by frequent small boluses or continuous infusion:* this is the mainstay of analgesia for severely injured patients who are intubated and ventilated. Patient-controlled analgesia (PCA) can be used for cooperative unintubated patients.
- *Thoracic epidural infusion of combined opioid and local anaesthetic agent (e.g. fentanyl 2 μg/mL + bupivicaine 0.125% at 5–15 mL/h):* this may be the preferred option for unintubated patients, particularly the elderly, if four or more ribs are fractured, or if there are cardiopulmonary co-morbidities. It may also be used to facilitate successful extubation of ventilated patients who still have significant analgesia requirements.
- *Intercostal nerve block:* this can be used if only a few lower ribs are fractured. Either a single bolus (20 mL of 0.5% bupivicaine) can be injected into one intercostal space, or smaller amounts can be injected at multiple levels. Repeated injections may be required.
- *Paravertebral block:* this is rarely used unless thoracic surgery is performed.
- *Non-steroidal anti-inflammatory agents:* these should be used only in fully resuscitated patients with normal renal function and no other contraindications.
- *Paracetamol:* this is given regularly except in the presence of hepatic dysfunction.

PNEUMONIA

Sepsis is the principal cause of late death after major trauma. Breach of the skin surface barrier, devitalised tissues and the presence of invasive drains and catheters make the trauma patient especially prone to bacterial invasion. In the chest-injured patient, pulmonary contusion, emergency intubation, shock, blood transfusion and the presence of extrathoracic injuries increase the risk of nosocomial pneumonia.

Early-onset pneumonia (within the first few days of hospitalisation) may result from aspiration at the time of injury, particularly after head injury. Common pathogens are *Haemophilus influenzae*, *Pneumococcus* and anaerobes. Later-onset nosocomial pneumonia is more likely to be due to aerobic Gram-negative bacilli and *Staphylococcus aureus*.

The diagnosis of pneumonia is suspected if there are new or progressive infiltrates on the chest radiograph and deterioration in respiratory status. However, new infiltrates may also be caused by pulmonary contusion, pleural fluid collections, atelectasis, aspiration and pulmonary oedema. Infection is supported by the presence of purulent sputum, new fever and leucocytosis. Confirmation depends on culture of tracheal aspirate, or bronchoscopic samples.[42]

Antibiotic therapy should be targeted at causative organisms. Prompt empirical antibiotics should be started in unstable patients, with re-evaluation at 48–72 hours.

Preventative measures include careful hand cleansing, reduced duration of intubation and ventilation, semirecumbent position, enteral nutrition, avoidance of excessive sedation or hyperglycaemia, and avoidance of prolonged prophylactic antibiotics.[42]

RETAINED HAEMOTHORAX AND EMPYEMA

Haemothorax that is not adequately drained within a few days becomes clotted and unable to drain via intercostal tube. The clot becomes organised and fibrosed with progressive pleural thickening (fibrothorax). This results in loss of lung volume, impaired pulmonary compliance and increased risk of empyema formation. Patients with persistent opacity on chest radiograph after intercostal tube placement should undergo ultrasound or CT imaging to determine whether a significant retained haemothorax is present.[12] Small haemothoraces (<300 mL) in clinically stable patients where the pleural cavity has not been breached may be observed. However, in the presence of respiratory compromise, suspected empyema, or retained haemothorax over 300 mL, further intervention is required. Several management options are available, but complete drainage should be achieved within 3–7 days, before the development of fibrothorax or empyema.

If the initial intercostal tube is poorly positioned, or blocked, a second tube may be placed through a different skin incision, preferably under ultrasound or CT guidance. In other circumstances a second intercostal tube should be avoided because of increased risk of empyema formation and high failure rate.[12,43] If the initial intercostal tube remains patent, evacuation of retained haemothorax can be attempted with intrapleural administration of thrombolytic agent,

after exclusion of a bleeding diathesis or intrathoracic organ injury.[12,44] Thrombolysis is most likely to be successful if attempted within 3 days of initial haemothorax. Streptokinase 250 000 units, or urokinase 100 000 units, in 100 mL saline is instilled into the intercostal tube for 4 hours each day until resolution of haemothorax with minimal further drain losses.[12,44] However, video-assisted thoracoscopic surgery (VATS) is the recommended approach in haemodynamically stable patients who can tolerate single-lung ventilation.[12,31,43] Failure of these techniques, or empyema formation, requires formal thoracotomy +/− decortication. VATS and thoracotomy allow direct inspection for a missed pulmonary, diaphragmatic or oesophageal injury.[31]

Patients who did not require initial intercostal tube drainage, but who subsequently develop respiratory compromise or opacification on chest radiograph, should be imaged with ultrasound or CT to look for delayed haemothorax. This should also prompt reconsideration of an occult injury to the diaphragm or an intrathoracic organ.[44]

FAT EMBOLISM SYNDROME

Fat embolism is very common in patients with long-bone fractures[45] and frequently causes oxygen desaturation, which may be severe and prolonged in patients with parenchymal lung injury.[46] However, fat embolism *syndrome*, with pulmonary, neurological and cutaneous sequelae, is rare. Treatment of fat embolism is supportive, but early resuscitation and fracture stabilisation are important preventative measures. [45] Early (<24 hours) intramedullary nailing is the fixation method of choice, resulting in fewer orthopaedic complications than other fixation methods, and fewer pulmonary complications than delayed surgery.[47] However, internal fixation may provoke further fat embolism, require a longer operative time and result in more blood loss than external fixation.[47] Thus in severely chest-injured patients, temporary stabilisation using external fixation with intramedullary nailing several days later is preferred.[47]

PROGNOSIS

Risk of death and length of intensive care stay depend on severity of chest injury, extent of extrathoracic injuries and pre-existing co-morbidities.[1,48] Initial physiological markers that predict adverse outcome are low Glasgow Coma Scale score, hypotension and high respiratory rate. In patients with severe blunt trauma the mortality is significantly higher with bilateral than with unilateral chest injuries, and depends more on the extent of parenchymal lung injury than the extent of chest wall injury.[49] Older age correlates strongly with worse outcome, even though the elderly are more likely to suffer rib fractures than parenchymal lung injury.[48,49] In the elderly the risk of death or pneumonia increases with each additional rib fractured.

Spinal injuries

Sumesh Arora and Oliver J Flower

Spinal cord injury (SCI) has immense consequences for patients, their families, healthcare resources and society. Initial management of SCI and prevention of secondary injury may make substantial differences to long-term functional outcome. SCI is best managed in specialised spinal injury units, with specialist medical, nursing and allied health expertise.[1,2] The prognosis for SCI has improved tremendously in the last 50 years and, despite their disability, survivors often report high levels of life satisfaction years after their injury.[3] Non-traumatic spinal cord injury, from a broad range of aetiologies, has an equal incidence to traumatic SCI and shares many clinical, pathological and management features with traumatic SCI. However, the specific differences in managing non-traumatic SCI are beyond the scope of this chapter, which will focus on traumatic SCI.

EPIDEMIOLOGY

Approximately 5% of trauma victims have spinal fractures, and 20% of these have SCI.[4] The incidence of traumatic SCI ranges from 2.3 to 83 cases per million population per year, with a prevalence ranging from 236 to 1800 per million population in developed countries.[5] Approximately 80% of SCI are male, usually in the 15–35 age group. Motor vehicle accidents are the commonest cause, followed by falls and sports-related injuries. The proportion of injuries relating to falls, especially in the over 60s, is increasing.[4,6] Pre-existing spinal pathology such as spinal canal stenosis or ankylosing spondylitis increases the risk of SCI from relatively minor trauma. Improved availability and quality of pre-hospital treatment has increased early survival and prevalence of SCI. The epidemiology of neurological level of injury varies dramatically depending on location. In developed countries, more than 50% of patients have cervical SCI, but developing countries report lower rates. This may be due to fewer of these patients surviving to hospital, as well as aetiological, geographical and economic global variation.[5] Approximately one-third of patients are tetraplegic and half have complete injuries, with both of these factors increasing in prevalence in recent years.[7]

PATHOGENESIS

APPLIED ANATOMY AND PHYSIOLOGY

The spinal cord extends from foramen magnum to approximately L1–L2 level. The conical lower end of the spinal cord is called the conus medullaris, from which a filament of connective tissue, known as filum terminale, continues inferiorly. The cauda equina refers to the bundle of spinal nerves for the lumbo-sacral segments that continue below the spinal cord. At the C1 level, the spinal cord occupies one-third of the spinal canal, whereas in the lower cervical and thoracic region it occupies 50% of the space. Compared with the spinal cord in the cervical and thoracic regions, the cauda equina is less susceptible to injury owing to a relatively larger canal size in the lumbar region. Corresponding to each intervertebral level, dorsal and ventral roots exit the spinal cord and join within the dural sac to form the spinal nerve. The spinal nerves run caudally within the spinal column until reaching the corresponding spinal levels, exiting through the spinal foramen. The sympathetic nerve supply originates from the intermediolateral column of segments T1–L2. The parasympathetic outflow originates from S2–S4 level and supplies the pelvic viscera. A cross-section of the spinal cord is shown in **Figure 78.1**.

SPINAL CORD INJURY

The pathophysiology of SCI is described as biphasic, consisting of primary and secondary phases.

PRIMARY INJURY

Direct mechanical injury may produce focal compression, laceration or traction injury to the cord. Actual transection is unusual. Ischaemic injury may result from interference to the segmental spinal arterial supply. Initial pathological changes include the traumatic severing of axons, blood vessels and cell membranes.[8,9]

SECONDARY INJURY

Local hypoperfusion and ischaemia begin at the site of injury, extending progressively over hours from the site

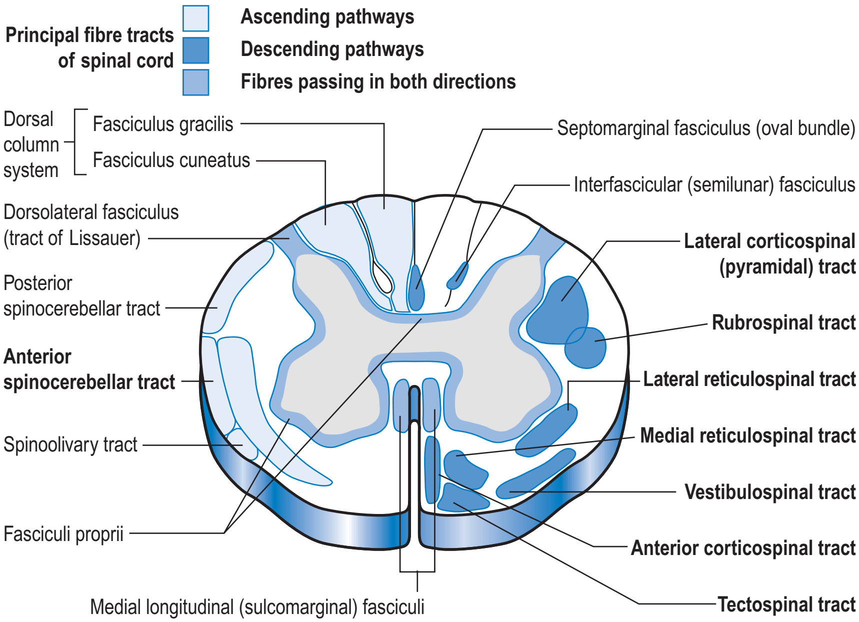

Figure 78.1 Cross-section of the spinal cord. *(From Principal Tracts of Spinal Cord, Image ID: 60477, published in Netter's Concise Neuroanatomy, Author: Michael Rubin, and Joseph E. Safdieh, Chapter: Gross Anatomy of the Brain and Spinal Cord, p 49, 2007.)*

of injury in both directions. There is loss of spinal cord autoregulation, often complicated by arterial hypotension in high SCI. Apart from ischaemia, other mechanisms may contribute to the secondary injury, including release of free radicals, reactive oxygen species, eicosanoids, calcium, proteases, phospholipases and excitotoxic neurotransmitters (e.g. glutamate).[8,9]

Petechial haemorrhages begin in the grey matter, progress over hours and may result in significant haemorrhage into the cord. There is oedema, cellular chromatolysis and vacuolation, and ultimately neuronal necrosis. Apoptosis, especially of oligodendrocytes, also occurs.[8] In the white matter vasogenic oedema, axonal degeneration and demyelination follow. Infiltration of polymorphs occurs in the haemorrhagic areas. Late coagulative necrosis and cavitation subsequently take place.[10]

INITIAL ASSESSMENT AND MANAGEMENT

The main principles in the early management of a spinal injury relate to the prevention of secondary injury and the provision of optimum conditions for neurological recovery. This includes prevention of secondary cord injury with immobilisation, prevention of hypoxia, defending blood pressure and avoiding metabolic abnormalities.

The general principles of managing severe trauma are outlined in Chapter 74. Resuscitation must occur synchronously with evaluation, initial investigations and management. The specific considerations in the acute setting are outlined in **Table 78.1**.

IMMOBILISATION

If a cervical SCI is suspected, the patient may have to be extricated from the scene of the accident. Manual stabilisation of the head in a neutral position is used with four people lifting and one controlling the head and neck. The neck is immobilised in a rigid, hard collar that should be applied without neck movement. The patient is placed supine on a rigid spine board with straps and occipital padding. Sandbags should be placed on either side of the head, and the head secured with the application of broad tape across the forehead. With a suspected thoracolumbar spinal injury, the patient is again lifted as a single unit or log rolled as necessary. Rigid collars and hard spinal boards cause rapid development of pressure areas. This risk can be minimised by transferring the patient off a hard board as soon as possible, safely rolling the patient every 2 hours, and by changing the hard collar if there could be any delay in cervical spine clearance. Of the collars available, evidence suggests the Miami J and Philadelphia collars restrict cervical range of movement more than Aspen or Miami J/Occian Back, and the Miami J and Miami J/Occian Back have the lowest levels of mandibular and occipital pressure.[11]

Complications of prolonged immobilisation and spinal precautions include cutaneous pressure

Table 78.1 Acute issues following SCI

ISSUE	PATHOPHYSIOLOGY RELEVANT TO SCI	MANAGEMENT
Need for intubation	Paralysis of muscles of respiration below NLOI Increased secretions and bronchospasm from loss of sympathetic innervation	Consider: • respiratory failure • decreased level of consciousness • transport with an unstable patient • need for surgery
Intubation	Excessive movement of neck in unstable cervical injury may cause further spinal cord damage	If intubation is urgent, rapid sequence induction and intubation with manual in-line stabilisation Minimise neck movement Video laryngoscopy improves view and minimises movement Consider awake fibreoptic intubation if time and expertise available
Hypotension	Loss of vasomotor tone below NLOI Bradycardia for NLOI above T_1 Traumatic abdominal or long-bone haemorrhage presents differently in patients insensate below the NLOI	Must exclude hypovolaemia/haemorrhagic shock Usually vasoplegia and bradycardia from SCI causing neurogenic distributive shock Give fluids initially Have low threshold for inserting central line and using norepinephrine (noradrenaline) Consider targeting a MAP of 85 mmHg (11.3 kPa) to maintain spinal cord perfusion
Bradycardia	Loss of cardiac sympathetic innervation (T_1–T_4)	May require anticholinergics (e.g. atropine), chronotropics (e.g. isoprenaline) or pacing
Neurological examination	NLOI and ASIA grade may be difficult to assess once patient is intubated	Obtain NLOI and ASIA grade if patient alert before sedation or intubation
Medications	Sedation may prevent accurate assessment of neurological status	Use short-acting sedatives and analgesics to permit ongoing neurological assessment Avoid paralytic agents if possible
Pressure area care	Loss of sensation and paralysis predisposes to early decubitus ulcers	Transfer off hard board Change collar to Miami J as soon as possible Roll every 2 hours
Hypothermia	Vasoplegia Loss of thermoregulatory control Exposure during resuscitation Pre-hospital environmental factors	External passive and active warming often required
Urinary retention	Paralysis of detrusor Loss of bladder sensation	Indwelling bladder catheter
Gastroparesis	Loss of gastrointestinal sympathetic innervation Ileus Gastroparesis	Nasogastric insertion
Refer and transfer	Better outcome in specialist spinal care centres	Early liaison and transfer to SCI specialist unit

NLOI = neurological level of injury.

ulceration, difficulties with the airway and intubation, potential venous obstruction affecting intracranial pressure, less options for central venous access, higher risk of VTE, and a higher risk of respiratory infections due to restricted physiotherapy, gastrostasis and an inability to provide optimal oral care.[12]

NEUROLOGICAL ASSESSMENT

TERMINOLOGY

The terminology for SCI has now been standardised:[13]

Tetraplegia: Greek nomenclature, preferred to quadriplegia, which is a mixture of Latin and Greek, is

defined as motor and/or sensory deficits affecting both upper and lower limbs, due to cervical SCI.

Paraplegia: motor and/or sensory deficits affecting only lower limbs due to SCI below the cervical levels.

Neurological level of injury (NLOI): the most caudal cord segment with normal motor and sensory function bilaterally. As differences often exist, it is preferred to describe the individual motor and sensory levels on each side (as the most caudal segments with normal motor and sensory function, respectively). In this context, normal motor function refers to a motor grade of 3, with all cephalad motor levels being grade 5. This is distinct from the skeletal or radiological level of injury.

Complete SCI: absence of both motor and sensory function in the lowest sacral segments (i.e. no anal tone and no sensation).

Zone of partial preservation: only used in describing complete (ASIA A) SCI. This refers to the spinal segments that have any motor or sensory function below the NLOI.

Spinal shock: the period of flaccid paresis and areflexia following a spinal injury, lasting from 48 hours to weeks, and ending with return of reflexes such as the bulbocavernosus reflex.[14]

Neurogenic shock: a form of distributive (cardiovascular) shock following SCI due to loss of sympathetic tone in peripheral vasculature.

A thorough neurological examination should be performed as early as feasible after presentation, prior to administration of any sedative or paralytic agents. The American Spinal Injury Association (ASIA) impairment scale[13] is the most validated instrument for diagnosing and classifying SCI. It is currently the only standardised neurological examination available that allows prognostication, and has sufficient inter-rater reliability for local and international data collection and comparison. A bilateral sensory and motor exam, including digital rectal examination, determines a single neurological level of injury (NLOI); completeness of injury and the ASIA grade (**Fig. 78.2**, **Box 78.1**) describes the grades of the ASIA impairment scale.[13] The physical exam should also include palpation of the spine for steps or gaps.

With conscious, alert patients, SCI may be obvious, with limb weakness, hypoaesthesia and absence of reflexes below the NLOI, vasodilatation, priapism, urinary retention and paralytic ileus. When assessing sensation, it should be remembered that the C4 dermatome can extend as low as the nipple line, misleading the examiner to believing the T_4 dermatome has sensation. An initial ASIA classification may reliably predict long-term motor outcome.[15] However, head or other injuries, pain, alcohol or the administration of analgesic or other drugs may make initial assessment impossible. Signs of SCI in unconscious or uncooperative patients include:

- response to pain above, but not below, a suspected level
- flaccid areflexia in the arms and/or legs
- elbow flexion with the inability to extend suggestive of cervical SCI
- paradoxical pattern of breathing with in-drawing of upper chest on inspiration (in the absence of upper respiratory tract obstruction or chest injury)
- inappropriate vasodilatation (in association with hypothermia, or in the legs but not the arms with thoracolumbar SCI)
- unexplained bradycardia, hypotension
- priapism
- loss of anal tone and reflexes.

Box 78.1 American Spinal Injury Association (ASIA) impairment scale

A	*Complete:* no sensory or motor function is preserved in the sacral segments S4–S5
B	*Incomplete:* sensory but not motor function is preserved below the neurological level and includes the sacral segments S4–S5
C	*Incomplete:* motor function is preserved below the neurological level, and more than half of key muscles below the neurological level have a muscle grade less than 3
D	*Incomplete:* motor function is preserved below the neurological level, and at least half of key muscles below the neurological level have a muscle grade greater than or equal to 3
E	*Normal:* sensory and motor function is normal

INCOMPLETE SCI

Incomplete SCI tends to occur in characteristic syndromes.[13] (See Fig. 78.1.)

SYNDROMES

- *Central cord:* weakness and sensory loss, greater in the arms than the legs – it typically follows a hyperextension injury with pre-existing canal stenosis, such as an elderly man falling onto his chin. Ischaemia or haematoma in the centre of the cord affects the cervical segments more due to the pattern of lamination of the corticospinal and spinothalamic tracts.
- *Anterior cord:* loss of motor function and pain and temperature sensation below the NLOI, with preservation of fine touch and proprioception – it is less common, typically following interruption of the blood supply to the anterior spinal cord.
- *Brown-Séquard:* ipsilateral loss of motor, proprioception and fine touch, with contralateral loss of pain and temperature sensation below the NLOI – it usually follows a penetrating SCI damaging only one-half of the spinal cord.
- *Conus medullaris:* sudden onset, symmetrical paraplegia with mixed upper and lower motor neuron findings, caused by injury at T12/L1.

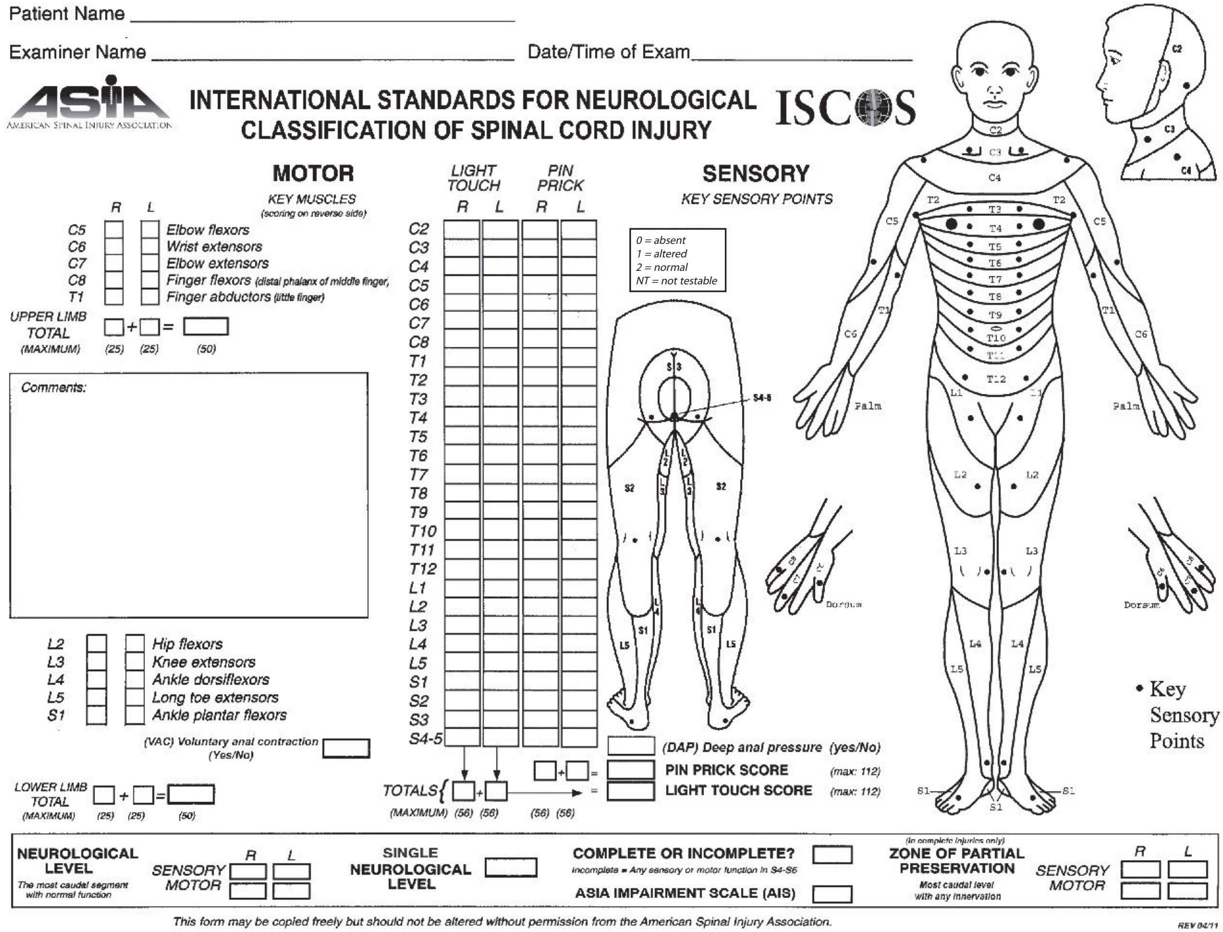

Figure 78.2 American Spinal Injury Association: International Standards for Neurological Classification of Spinal Cord Injury, revised 2011. *(From American Spinal Injury Association. International Standards for Neurological Classification of Spinal Cord Injury, revised 2011.)*

- *Cauda equina:* often asymmetrical, lower motor neuron lower limb weakness with saddle area hypoaesthesia or paraesthesia, with bladder and bowel areflexia – it is caused by injuries below L1 damaging the lumbosacral nerve roots.

ASSOCIATED INJURIES

Cervical spine injury/tetraplegia

Overall with major trauma the incidence of cervical spine injury (CSI) is 1–3%. However, 2–10% of patients with head injuries have a CSI. The more severe the head injury, the more likely CSI is to be present. Patients with head injuries should be assumed to have a CSI until proved otherwise. Of patients with a cervical SCI, 25% have some degree of head injury, with 2–3% having a severe injury.[8]

Thoracolumbar spine injury/paraplegia

Chest injuries are often present and are difficult to assess with the inability to take an erect chest X-ray, and the presence of a mediastinal haematoma associated with the vertebral injury. Computerised tomography (CT) of the chest may be used to assess other chest injuries, with contrast to exclude aortic injuries. There should be a high index of suspicion of abdominal injuries, as the lack of sensation, hypotension and bradycardia from the SCI may mask the usual presentation. Abdominal ultrasound and CT are usually required to delineate these injuries.

IMAGING

IS IMAGING REQUIRED?

Some trauma patients may not require cervical spinal imaging and the inherent risks that this entails. Two clinical decision tools are used in this context: The National Emergency X-Radiography Utilization Study (NEXUS) criteria and the Canadian C-Spine rules. NEXUS suggests cervical spine imaging is

Muscle Function Grading

0 = total paralysis

1 = palpable or visible contraction

2 = active movement, full range of motion (ROM) with gravity eliminated

3 = active movement, full ROM against gravity

4 = active movement, full ROM against gravity and moderate resistance in a muscle specific position.

5 = (normal) active movement, full ROM against gravity and full resistance in a muscle specific position expected from an otherwise unimpaired peson.

5*= (normal) active movement, full ROM against gravity and sufficient resistance to be considered normal if identified inhibiting factors (i.e. pain, disuse) were not present.

NT= not testable (i.e. due to immobilization, severe pain such that the patient cannot be graded, amputation of limb, or contracture of >50% of the range of motion).

ASIA Impairment (AIS) Scale

☐ **A = Complete.** No sensory or motor function is preserved in the sacral segments S4-S5.

☐ **B = Sensory Incomplete.** Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4-S5 (light touch, pin prick at S4-S5: or deep anal pressure (DAP)), AND no motor function is preserved more than three levels below the motor level on either side of the body.

☐ **C = Motor Incomplete.** Motor function is preserved below the neurological level**, and more than half of key muscle functions below the single neurological level of injury (NLI) have a muscle grade less than 3 (Grades 0-2).

☐ **D = Motor Incomplete.** Motor function is preserved below the neurological level**, and at least half (half or more) of key muscle functions below the NLI have a muscle grade ≥ 3.

☐ **E = Normal.** If sensation and motor function as tested with the ISNCSCI are graded as normal in all segments, and the patient had prior deficits, then the AIS grade is E. Someone without an initial SCI does not receive an AIS grade.

**For an individual to receive a grade of C or D, i.e. motor incomplete status, they must have either (1) voluntary anal sphincter contraction or (2) sacral sensory sparing with sparing of motor function more than three levels below the motor level for that side of the body. The Standards at this time allows even non-key muscle function more than 3 levels below the motor level to be used in determining motor incomplete status (AIS B versus C).

NOTE: When assessing the extent of motor sparing below the level for distinguishing between AIS B and C, the ***motor level*** on each side is used; whereas to differentiate between AIS C and D (based on proportion of key muscle functions with strength grade 3 or greater) the ***single neurological level*** is used.

Steps in Classification

The following order is recommended in determining the classification of individuals with SCI.

1. Determine sensory levels for right and left sides.
2. Determine motor levels for right and left sides.
Note: in regions where there is no myotome to test, the motor level is presumed to be the same as the sensory level, if testable motor function above that level is also normal.
3. Determine the single neurological level.
This is the lowest segment where motor and sensory function is normal on both sides, and is the most cephalad of the sensory and motor levels determined in steps 1 and 2.
4. Determine whether the injury is Complete or Incomplete.
(i.e. absence or presence of sacral sparing)
If voluntary anal contraction = **No** *AND all S4-5 sensory scores =* **0** *AND deep anal pressure =* **No,** *then injury is COMPLETE. Otherwise, injury is incomplete.*
5. Determine ASIA Impairment Scale (AIS) Grade:

Is injury Complete? If **YES,** AIS=A and can record ZPP (lowest dermatome or myotome on each side with some preservation)

NO ↓

Is injury motor Incomplete? If **NO,** AIS=B (Yes=voluntary anal contraction OR motor function more than three levels below the motor level on a given side, if the patient has sensory incomplete classification)

YES ↓

Are at least half of the key muscles below the single neurological level graded 3 or better?

NO ↓ AIS=C

YES ↓ AIS=D

If sensation and motor function is normal in all segments, AIS=E
Note: AIS E is used in follow-up testing when an individual with a documented SCI has recovered normal function. If at initial testing no deficits are found, the individual is neurologically intact; the ASIA Impairment Scale does not apply.

Figure 78.2, cont'd

indicated for patients with trauma unless they meet all of the following criteria:[16]

- no posterior midline cervical spine tenderness
- no evidence of intoxication
- a normal level of alertness
- no focal neurological deficit
- no painful distracting injuries.

NEXUS criteria have a very high sensitivity (99.6% for significant injuries) if used as initially intended, although the specificity is only 12.9%. They require there to be no evidence of any intoxication (including even an odour of alcohol), an alert level of consciousness sufficient to allow *three-object recall at 5 minutes*, no focal neurological deficits and there should be no painful distracting injuries. This subjective component includes any long-bone fractures, de-gloving injuries, deep lacerations, visceral injuries, crush injuries, large burns or any injury that causes any acute functional impairment. The Canadian C-Spine rules have a higher degree of sensitivity (100%) and specificity (45%) but were based on a smaller cohort of patients than NEXUS.[16] Again, they define only which patients may be clinically cleared without imaging.

IMAGING MODALITIES

PLAIN RADIOGRAPHS

Adequate, three-view combination plain radiography misses injuries of the spinal column in both alert and obtunded patients, with a pooled sensitivity of detecting significant injuries of 52%.[17] Despite reducing thyroid radiation exposure in comparison to CT, plain radiography has no role in this context, unless other modalities are not available.[18]

DYNAMIC STUDIES (e.g. DYNAMIC FLUOROSCOPY OR FLEXION/EXTENSION RADIOGRAPHY)

This imaging modality visualises the relevant anatomy poorly[19] and has a low sensitivity to detect injury.[20] It is labour- and resource-intensive[21] and has now been superseded by CT and MRI.

COMPUTERISED TOMOGRAPHY

CT technology has improved considerably in recent years, with multi-detector row CT (MDCT) offering sensitivity of detecting spinal injuries, including ligamentous injury, close to 100%.[22] MDCT is readily available, easily performed as part of a polytrauma evaluation and

is more time- and cost-effective than plain radiography. However, MDCT may miss some significant and unstable injuries (subsequently detectable by MRI) in approximately 4%, with 0.29% requiring surgical stabilisation. Other disadvantages include significant thyroid radiation exposure and transport of a trauma patient to CT.[12]

MAGNETIC RESONANCE IMAGING (MRI)

For investigating suspected myelopathy and cord injury, MRI provides superior imaging to any other modality.[23] It is the most sensitive screening test available to detect soft-tissue and ligamentous injuries that could contribute to instability of the cervical spine[24] and MR angiography may detect associated vertebral artery injury. However, MRI has a rate of false positives as high as 40%,[25] which may result in unnecessary and detrimental immobilisation, transfers and imaging in patients who have no injury. Complications of prolonged immobilisation are a significant cause of morbidity and mortality. Timing of MRI is another contentious issue as, with time, the MR signal may change due to a decrease in ligamentous oedema. The Eastern Association for the Surgery of Trauma guidelines recommend that MRI should be performed within 72 hours.[26] However, there is only limited evidence that delay between injury and imaging results in a false-negative MRI.[27]

AN APPROACH TO IMAGING

There is currently no universal consensus. Following trauma, if there is evidence of any new neurological deficit attributable to a spinal injury then an urgent MRI should be performed. If there is no neurological deficit but the other conditions of the CCCR or NEXUS rules are not met, then high-resolution MDCT of the entire spine is indicated. For the obtunded blunt trauma patient who is likely to be unassessable for a prolonged period, an MRI may follow the MDCT.

Policy for the use of MRI in this context should be discussed at an institutional level, with the knowledge that a policy with MDCT alone may miss a small percentage of injuries that would otherwise have required intervention, but the false-positive rate of MRI results in significant morbidity to patients with no injuries who are kept immobilised.[12]

INTENSIVE CARE MANAGEMENT OF SCI

PREVENTION OF SECONDARY NEUROLOGICAL INJURY AFTER SCI

Spinal cord compression may occur owing to misalignment of spine, oedema or haemorrhage. Incomplete injury with spinal cord compression should be urgently decompressed. Stability is the ability of the spine, under physiological loads, to limit patterns of displacement, which would result in neurological injury, pain, or deformity.[28] It is affected by fracture morphology and osteo-ligamentous integrity. Most unstable spinal injuries require operative intervention. Where indicated, early surgery within 24 hours of injury is safe, may improve neurological outcome, reduces length of stay in acute care, permits early mobilisation and commencement of DVT prophylaxis and lowers hospital cost.[29] Most spinal surgeons prefer to operate as early as possible in patients with incomplete or cervical spinal cord injury.

Many pharmacological agents have been investigated in secondary injury to aid recovery of damaged neurons; however, none of these have proven successful. NASCIS 2[30] and NASCIS 3[31] were the largest trials that investigated the effects of corticosteroids in SCI. They both were negative studies, showing no significant difference in motor score between treatment groups at any time points. Post-hoc subgroup analysis of these data suggesting neurological outcome benefit was fundamentally flawed. The lack of evidence of efficacy and the adverse effects of steroids such as sepsis (particularly pneumonia), detrimental effects on concomitant head injury, risk of gastrointestinal bleeding and pancreatitis, has seen steroid use fall out of favour in recent years. Other agents that have been investigated with no evidence of benefit include GM-1 ganglioside, tirilazad, naloxone and nimodipine.

There is weak evidence that a mean arterial pressure (MAP) >85 mmHg (11.3 kPa) should be maintained for up to 7 days following injury,[32] theoretically improving cord perfusion pressure and preventing secondary injury. After initial fluid resuscitation vasopressors such as norepinephrine (noradrenaline) are commonly required to meet this target. Induced hypothermia has been reported to be beneficial in case reports, but there is not enough evidence to recommend this intervention currently.[33] Fever may worsen outcome and normothermia should be maintained.

RESPIRATORY DYSFUNCTION

Respiratory dysfunction is a major cause of morbidity after SCI, especially after cervical SCI. The diaphragm, external intercostals, scalene and sternocleidomastoid are the key muscles of inspiration. Quiet expiration is passive, but forceful expiration and cough require the abdominal muscles, the interosseous part of the internal intercostals, lattisimus dorsi, serratus posterior and inferior, triangularis sterni and quadratus lumborum. The effect of SCI on respiratory function depends upon the NLOI. Various effects of cervical SCI on respiratory function are listed in **Table 78.2**. The diaphragm is innervated by C3–5. If the NLOI is above C5, the sternocleidomastoid (innervated by cranial nerve XI and anterior rami of C2, 3) and scalenus medius and posterior (innervated by C3–4) become important muscles of inspiration. The abdominal wall muscles are innervated by T_7–L1, and if the NLOI is above this the cough is generated only by the muscles of the upper chest, particularly the pectoralis major.[34]

Table 78.2 Effect of cervical SCI on respiratory function

Decreased vital capacity	Paralysis of diaphragm and intercostal muscles Distortion of rib cage in inspiration due to paralysed diaphragm
Reduced compliance of lungs and chest wall	Spasticity of intercostal muscles Altered articulation of ribs to sternum and vertebrae Low functional residual capacity Atelectasis Possible alteration of surfactant
Increased abdominal compliance	Paralysis of abdominal muscles
Increased bronchial tone and secretions	Sympathetic denervation
Poor cough	Reduced vital capacity Abdominal muscle paralysis
Sleep disordered breathing (develops within 6 months)	Unknown cause Increased adipose tissue around neck Anti-spasticity drugs

RESPIRATORY MANAGEMENT AFTER CERVICAL SPINAL CORD INJURY

Intubation may be required for respiratory failure, secretion clearance, imminent surgery, decreased level of consciousness or because of other injuries. Almost 75% of patients with cervical SCI will require intubation and mechanical ventilation.[35]

The cervical spine should be immobilised during endotracheal intubation. If time and expertise are available, awake fibreoptic intubation minimises the movement of the neck. Video laryngoscopes may improve glottic view when the neck is immobilised. Direct laryngoscopy with manual inline stabilisation does not eliminate all movement at the cervical spine, but there is no evidence that it is associated with neurological outcomes that are worse than other intubation techniques.

In the initial period after cervical SCI, ventilator settings are dictated by associated injuries and other co-morbidities. For example, in patients with severe traumatic brain injury, normocapnia should be maintained. Once acute issues have resolved, mechanical ventilation should be tailored to SCI. Baseline spirometry should be obtained to allow monitoring of progress.

Tidal volumes (V_T) in excess of 10 mL/kg are often used in patients with cervical SCI. The rationale for high V_T ventilation is to prevent atelectasis and the common sensation of 'air hunger' experienced following SCI. This avoids the need for high-level PEEP that may lower the position of diaphragm to one of mechanical disadvantage. In many spinal centres, V_T of 10–20 mL/kg is used routinely.[36] With high V_T, dead space must be incorporated into the circuit to avoid hypocapnoea. Another approach is to use more conventional V_T and higher PEEP to prevent atelectasis. Until better-quality evidence is available, an individualised approach to ventilator settings should be used.

Box 78.2 Checklist prior to extubation

1. No further procedure or imaging outside ICU anticipated in next 24 hours
2. No significant hypoxia or reversible respiratory pathology
3. Ability to tolerate non-invasive ventilation
4. No contraindication for the assist cough or chest physiotherapy (e.g. rib fractures, major laparotomy)
5. Minimal respiratory secretions
6. Negative inspiratory force >20 cmH_2O
7. Vital capacity >10 mL/kg
8. Presence of cuff leak (particularly after spinal fixation by anterior approach)
9. Airway plan and equipment ready for re-intubation

Extubation after mechanical ventilation in patients with cervical SCI requires careful consideration of several factors (**Box 78.2**), with failure likely to necessitate a tracheostomy. Extubation failure is commonly due to retained, excessive secretions, inadequate cough and sputum plugs. Patients may benefit from extubation to non-invasive ventilation directly, which may be required for several days post extubation. A variety of non-invasive ventilation interface devices should be available and nasal skin should be protected from developing pressure ulcers. Aggressive chest physiotherapy and assisted coughing are required to clear secretions.

The tracheostomy rate after cervical SCI varies between 20 and 60%. Complete injuries above C5 usually require tracheostomy.[37] A high NLOI, complete SCI, associated facial fractures, thoracic trauma and emergency intubation are associated with need for tracheostomy. Percutaneous tracheostomy is as safe as surgical tracheostomy.[38] Early tracheostomy may reduce the duration of mechanical ventilation and ICU length

of stay and it does not increase the risk of wound or implant infection even after anterior spinal fixation.[39]

Weaning from MV after cervical SCI may take considerable time. In some centres, high-level tetraplegics are cared for in chronic respiratory care facilities rather than ICUs. It is important that a long-term weaning strategy is agreed upon and adhered to by all members of the multidisciplinary team. Accurate neurological assessment, progressive ventilator-free breathing guided by vital capacity, adequate rest periods with controlled ventilation, and secretion control with aggressive physiotherapy are associated with successful weaning.[40] Inspiratory muscle training uses an inspiratory resistor to increase the strength of inspiratory muscles. Although more studies are needed to delineate clearly the role of inspiratory muscle training in weaning of patients with cervical SCI, its use makes physiological sense and is being used increasingly.[41] It should be remembered that most patients with cervical SCI ventilate more easily when supine compared with being upright, as their abdominal contents can push the diaphragm up into a position of better mechanical advantage in supine position. An abdominal binder may be used in the sitting position, which also helps in this regard.

Inhaled anticholinergics and β_2-agonists reduce airway resistance but have not been shown to improve success of weaning. Anabolic steroids like oxandrolone do not lead to significant improvement in respiratory function and may cause hepatotoxicity and dyslipidaemia. Phrenic nerve or direct diaphragmatic-pacing systems are occasionally used for respiratory support in high-level tetraplegics.

The NLOI is the strongest predictor of successful weaning.[42] Patients with complete injuries at or above C3 are likely to need permanent ventilation. Early identification of patients who cannot be weaned helps reduce their ICU length of stay and expedites the arrangements for equipment and care personnel required for home ventilation or transfer to a chronic respiratory care facility. Overall, approximately 2% of patients with SCI, mostly with complete injuries at C1–C4, require lifelong ventilation.[43]

CARDIOVASCULAR DYSFUNCTION AFTER SCI

The heart receives its sympathetic innervation from the upper thoracic segments via the superior, middle and inferior cervical ganglions. Vasomotor tone of the peripheral vasculature is also controlled by segmental sympathetic innervation. The heart's parasympathetic innervation comes from the vagus, and therefore is not affected by SCI. Following SCI, loss of sympathetic supply and unopposed vagal activity may cause profound vasoplegia combined with bradycardia, resulting in hypotension and neurogenic shock. This occurs in 19% of patients with cervical and 7% of thoracic SCI.[44] Other causes of hypotension, particularly hypovolaemic shock, must be excluded before a diagnosis of neurogenic shock is made. Bradycardia and even asystole may occur during routine ICU procedures like endotracheal suction or repositioning in bed in patients with a cervical NLOI. This phenomenon occurs most commonly in the first week and generally resolves within 2–6 weeks after injury.[45]

CARDIOVASCULAR COMPLICATIONS

AUTONOMIC DYSREFLEXIA

Autonomic dysreflexia (AD) is a medical emergency characterised by acute hypertension due to severe sympathetic stimulation in patients with injuries above T6. It occurs following the resolution of spinal shock (once reflexes have returned) and is a frequent cause for admission to ICU. AD occurs due to dysregulated sympathetic activation leading to intense vasoconstriction below the level of lesion. Compensatory parasympathetic activation leads to bradycardia, vasodilatation and sweating above the NLOI. Other symptoms include headache, blurred vision, nausea and nasal congestion. The precipitants, investigations and treatments of precipitating factors are outlined in **Table 78.3**.

Initial management includes primarily detecting and treating the precipitant, sitting the patient up (to induce an orthostatic hypotensive response), loosening tight clothing and antihypertensives. Sublingual or transdermal glyceryl trinitrate is used initially. Sublingual captopril or oral prazocin may be used in unresponsive patients before intravenous agents such as sodium nitroprusside or glyceryl trinitrate infusions are used. Invasive BP monitoring is required if infusion of intravenous agents is used. Some patients may develop chronic, severe AD requiring multiple classes of antihypertensive. It must be remembered that, in the setting of chronic hypotension following SCI, systolic blood pressure of >150 mmHg (≈20 kPa) is life-threatening,[46] and may lead to intracerebral or retinal haemorrhage or myocardial ischaemia.

VENOUS THROMBOEMBOLISM

If inadequate or no prophylaxis is used, venous thromboembolism (VTE) following SCI has a very high incidence of up to 100%.[47] With prophylaxis, this incidence has reduced; however, 5% of patients with SCI will still develop VTE,[48] and pulmonary embolism (PE) remains a leading cause of death. The use of low-molecular-weight heparin (LMWH) or unfractionated heparin in combination with mechanical measures for thromboprophylaxis is recommended. LMWH is superior to subcutaneous heparin in decreasing the incidence of deep-vein thrombosis, but not PE, and carries less bleeding complications. Commencement of adequate VTE prophylaxis is easier if all planned surgical procedures can occur as soon as practicable. The risk of venous thromboembolism increases significantly if prophylaxis is started more than 72 hours after the injury.[49] If pharmacological VTE prophylaxis is contraindicated, a retrievable inferior vena cava filter should be considered.[50]

Table 78.3 Precipitants, investigations and treatment of autonomic dysreflexia[56]

PRECIPITANT	INVESTIGATION AND TREATMENT
Bladder distension (cause in 75–85%)	Insert or change bladder catheter
Faecal impaction (cause in 13–19%)	Digital examination Laxatives Enema Manual disimpaction
Urinary tract calculi	CT of urinary tract Cystoscopy or surgery to remove calculi
Urinary tract infection	Urinary microscopy and culture Appropriate antibiotics
Haemorrhoids or anal fissure	Laxatives Dietary management
Decubitus ulcers, with or without infection	Rule out underlying osteomyelitis Pressure care Consider plastic surgery Consider antibiotics
Foot disease including ingrown toenails	Nail care
Procedures (e.g. suprapubic catheter insertion, cystoscopy, urodynamic studies)	Spinal anaesthesia may prevent AD
Heterotopic ossification	Bone scintigraphy Measure C-reactive protein and creatine kinase Physiotherapy Surgery
Pelvic stimulation (sexual activity, menstruation, labour)	Education Be prepared in peripartum period
Skeletal fractures	High index of suspicion below NLOI

NLOI = neurological level of injury.

MUSCULOSKELETAL COMPLICATIONS

Muscle spasticity is a common but late issue. It develops after resolution of spinal shock and is characterised by increased muscle tone, hyperreflexia and muscle spasms below the NLOI. The initial treatment is enteral baclofen, the side-effects of which include sedation, fatigue and confusion that may interfere with weaning from mechanical ventilation or participation in a rehabilitation programme. Intrathecal baclofen, gabapentin, pregabalin and benzodiazepines may also be used for severe spasticity.[46] Physiotherapy measures are needed to preserve a full range of movement in paralysed joints and to prevent contractures. Special attention should be given to hand and shoulder physiotherapy after cervical SCI to preserve maximum functionality.

CHRONIC PAIN
